Asymptotically Optimal Feedback Protocol Design for Cognitive Multiple Access Channels

Ehsan Nekouei, *Student Member, IEEE*, Hazer Inaltekin, *Member, IEEE* and Subhrakanti Dey, *Senior Member, IEEE*

Abstract

In cognitive multiple access networks, feedback is an important mechanism to convey secondary transmitter primary base station (STPB) channel gains from the primary base station (PBS) to the secondary base station (SBS). This paper investigates the optimal sum-rate capacity scaling laws for cognitive multiple access networks in feedback limited communication scenarios. First, an efficient feedback protocol called K-smallest channel gains (K-SCGs) feedback protocol is proposed in which the PBS feeds back the K_N smallest out of N STPB channel gains to the SBS. Second, the sum-rate performance of the K-SCG feedback protocol is studied for three network types when transmission powers of secondary users (SUs) are optimally allocated. The network types considered are total-power-and-interference-limited (TPIL), interference-limited (IL) and individual-power-and-interference-limited (IPIL) networks. For each network type studied, we provide a sufficient condition on K_N such that the K-SCG feedback protocol is *asymptotically* optimal in the sense that the secondary network sum-rate scaling behavior under the K-SCG feedback protocol is the same with that under the full-feedback protocol. We allow distributions of secondary-transmitter-secondary-base-station (STSB), and STPB channel power gains to belong to a fairly general class of distributions called class $\mathcal{C}$-distributions that includes commonly used fading models. It is shown that for $K_N = N^{\delta}$ with $\delta \in (0,1)$, the K-SCG feedback protocol is asymptotically optimal in TPIL networks, and the secondary network sum-rate scales according to $\frac{1}{n_h}\log\log(N)$, where n_h is a parameter obtained from the distribution of STSB channel power gains. In this case, it is also shown that the average interference power at the PBS can be made arbitrarily small without losing anything from this optimal sum-rate scaling behavior. For IL networks, the K-SCG feedback protocol is asymptotically optimal if $K_N = O(1)$. In this case, the secondary network sum-rate scales optimally according to $\frac{1}{\gamma_g}\log(N)$, where γ_g is a parameter obtained from the distribution of STPB channel gains. Finally, for IPIL networks, it is proven that the K-SCG feedback protocol is asymptotically optimal if $K_N = O(1)$, and the secondary network sum-rate scales according to $\min\left(1, \frac{1}{\gamma_g}\right)\log(N)$. An extensive simulation and numerical study is also performed to illustrate the established sum-rate capacity scaling laws for finite networks.

I. INTRODUCTION

A. Background and Motivation

The electromagnetic radio spectrum is a limited communication resource. This fact makes its allocation and exploitation one of the prime concerns to accommodate increasingly more data-rate-intense wireless services and next generation wireless systems in today's already vastly crowded spectrum. Part of the reason for the perceived crowdedness of the radio spectrum is the current practice of managing it, which is the legacy *command-and-control* regulation [1]. This is a static regulatory approach to the spectrum management based on exclusive usage rights assigned to a number of licensees. Being static by its nature, the command-and-control approach cannot utilize spatio-temporal spectrum usage characteristics of the incumbent users (alternatively called: primary users or PUs), and therefore cannot opportunistically assign radio spectrum to other unlicensed third parties (alternatively called: cognitive users, secondary users or SUs).

As a response to the sheer pressure of having a more dynamic means of managing spectrum and exploiting likely spectrum holes, there emerged the idea of cognitive radio technology as a revolutionary "disruptive but unobtrusive" technique [2]. Roughly speaking, it alleviates the spectrum scarcity problem by allowing cognitive users to share the same bandwidth with the PUs provided that their transmissions do not cause harmful degradation to the primary transmission. Various signal processing, information-theoretic and protocol related aspects of the cognitive radio networks have been investigated extensively over the last decade, *e.g.*, see [3]-[5] and references therein. Among many other issues, one of the recurrent themes appearing in most of the earlier papers on cognitive radio is the awareness of cognitive transmitters (or, the awareness of a central entity to perform scheduling and resource allocation among SUs) about the channel states of PUs and SUs.

Briefly, channel side information at the cognitive transmitters is necessary for the proper completion of the cognition cycle, and the harmonious operation of PUs and SUs in a given frequency band. However, for large numbers of SUs, this requirement puts an excessive and impractical feedback burden on the backhaul link between the primary and secondary networks, which leads to the following research question of interest here: What are the optimal capacity scaling laws for cognitive secondary networks containing large numbers of SUs when secondary-transmitter-primary-base-station (STPB) channel states are *only partially* available? The current paper addresses this question for the specific case of a cognitive multiple access (CMAC) network in which the sum-rate capacity of the CMAC network is the primary performance figure of interest, and the STPB channel states are partially available at the secondary base-station (SBS). Here, "partially available" means only a subset of channel states are available at the SBS. The SBS performs jointly optimum power control and scheduling policy to extract the maximum possible sum-rate from the SUs based on the available channel side information and subject to interference power constraints at the primary base-station (PBS).

More specifically, we consider a CMAC network in which N SUs transmit data to a common SBS, and interfere with the signal reception at a PBS at the same time. This is the commonly used underlay paradigm for the coexistence of primary and secondary networks [4], which is also known as the spectrum sharing technique [6]. For such communication instances, availability of STPB channel gains of *all* SUs at the secondary network is a frequent assumption in the cognitive radio literature, *e.g.*, see [7]-[10]. While this assumption is crucial for the SBS to manage the secondary network interference power at the PBS as well as to implement jointly optimum power control and scheduling policy, it places an extra burden on the primary network. In order STPB channel gains to be available at the SBS, the PBS should estimate STPB channel gains for all SUs and convey them to the SBS by means of a primary-secondary feedback link (PSFL), *i.e.*, backhaul link, or by means of a band manager mediating communication between primary and secondary networks [6], [11], [12]. In either case, the feedback is required, and the capacity of the feedback link is limited in general. Hence, for large numbers of SUs, it becomes impractical for the PBS to convey all STPB channel gains to the SBS within the channel coherence time due to various physical restrictions on the communication system of interest such as feedback link capacity limitations and energy constraints.

Here, we show that the capacity of the backhaul link does not act as a primary bottleneck on the sum-rate capacity scaling behavior of CMAC networks if the user selection for feedback is performed intelligently at the PBS. That is, we find that the secondary networks can achieve the optimal sum-rate capacity scaling laws even when the STPB channel gains are partially available at the SBS for some of the strategically chosen SUs, *i.e.*, see Theorems 1, 3 and 4 in Section III for greater details. Although the total feedback load (*i.e.*, the number of SUs whose channel states to be fed back to the SBS) grows large with the total number of SUs, the rate of increase of the feedback load can be made arbitrarily smaller than the rate of increase of the total number of SUs. From a practical point of view, this finding implies a significant primary-secondary feedback load reduction for cognitive radio networks with large numbers of SUs without any significant first-order reduction in the secondary network data rate. Our results further indicate that secondary networks can coexist with primary networks by causing *almost* no interference, *i.e.*, see Theorem 2 in Section III. Through the characterization of the scaling behavior of the secondary network sum-rate in terms of feedback link capacity, fading parameters and the number of SUs, our results shed light on the fundamental tradeoffs between the secondary network sum-rate capacity and the feedback link capacity. They also provide critical engineering insights for the design of primary-secondary feedback protocols and for cognitive radio network planning.

B. Main Contributions in Detail

Design of feedback reduction policies for the PSFL is a challenging issue due to dependence of multiuser diversity gains and the interference management task on the knowledge of STPB channel gains. We consider that the PBS is able to send the STPB channel gains of at most K_N SUs to the SBS, where K_N is an integer smaller than or equal to N and possibly changing as a function of N.[1] $K_N = N$ case is named as the full-feedback protocol in which the SBS has the perfect knowledge of all STPB channel gains to implement user scheduling and power control. K_N can be interpreted as our modeling parameter to numerically designate the feedback capability of the PSFL, *i.e.*, the more capacity the PSFL has, the larger K_N is. In the absence of any knowledge about the secondary-transmitter-secondary-base-station (STSB) channel gains, the best strategy for the PBS is to pick the least harmful SUs by feeding back the channel gain g_i of the SU-i if and only if $g_i \leq g_{K_N:N}$, where $g_{K_N:N}$ is the K_Nth smallest value in the set $\{g_i\}_{i=1}^N$. Formally speaking, $g_{K_N:N}$ is the K_Nth order statistic for the collection of random variables $\{g_i\}_{i=1}^N$. We refer to this feedback policy as the *K-smallest channel gain* (K-SCG) feedback protocol. Hence, using the K-SCG feedback protocol, the PBS feeds back the K_N smallest fading gains in the STPB channel to the SBS as well as the corresponding users indices. To avoid harmful interference at the PBS, the SBS schedules a SU only if its STPB channel gain is made available at the SBS.

---

[1] Although we do not show the dependence of K on N, it should be understood that K is a function of N in the remainder of the paper.

This paper focuses on the effect of the K-SCG feedback protocol on the throughput scaling for three types of secondary networks: Total-Power-And-Interference-Limited (TPIL), Interference-Limited (IL) and Individual-Power-And-Interference-Limited (IPIL) networks when transmit powers of SUs are optimally allocated. In the case of TPIL networks, transmit powers of SUs are limited by an average total power constraint as well as a constraint on the average total interference power that they cause to the PBS. On the other hand, transmit powers of SUs are limited by a constraint only on the average total interference power at the PBS for IL networks. In the case of IPIL networks, transmit powers of SUs are limited by individual average power constraints as well as a constraint on the average total interference power at the PBS. For each network type studied, we provide a sufficient condition on K_N such that the K-SCG feedback protocol is *asymptotically* optimal, *i.e.*, the sum-rate capacity scaling behavior under the K-SCG feedback protocol is the same with that under the full-feedback protocol.

Due to mathematical intractability of the cumulative distribution functions (CDF) of random variables emerging in secondary network capacity calculations, secondary network capacity scaling laws have been mainly investigated for specific fading distributions for STSB and STPB channel gains such as Rayleigh distribution in the literature, *e.g.*, see [8], [9], [14] and [15]. Different from these works, this paper studies the sum-rate scaling behavior of secondary networks under both K-SCG and full-feedback protocols when distributions of STSB and STPB channel gains are arbitrarily chosen from a more general class of distribution functions called class $\mathcal{C}$-distributions (*i.e.*, see Definition 2.1). The class $\mathcal{C}$-distributions contains distribution functions that decay double-exponentially and vary regularly around the origin. It covers the most common fading distributions such as Rayleigh, Rician, Nakagami-m and Weibull distributions. In Appendix A, we show that the concentration behavior of the extreme order statistic of an independent and identically distributed (i.i.d.) sequence of random variables is characterized by the asymptotic tail behavior of the CDF common to all of them. This finding enables us to study the capacity scaling laws for secondary networks under class $\mathcal{C}$ distribution functions for STSB and STPB channel gains.

Our results for the TPIL networks indicate that the secondary network throughput under the K-SCG and full-feedback protocols scales according to $\frac{1}{n_h}\log\log(K_N)$ and $\frac{1}{n_h}\log\log(N)$, respectively. n_h a is parameter determined from the asymptotic tail behavior of STSB channel power gains. For example, n_h is equal to 1 for

Rayleigh, Rician and Nakagami-m distributions, whereas it is equal to $\frac{c}{2}$[1] for the Weibull distribution. Consequently, for $K_N = N^\delta$ where $0 < \delta < 1$, the secondary network throughput scales as $\frac{1}{n_h} \log \log(N)$. Hence, the secondary network can achieve the same throughput scaling as with the full channel state information (CSI) case for any δ arbitrarily close to zero. To put it in other words, the rate of growth of the feedback load can be made arbitrarily small when compared to the rate of growth of the number of SUs without any sacrifice from the optimal sum-rate scaling behavior.

For $K_N = o(N)$, we show that the interference power at the PBS converges to zero almost surely and also in mean as N tends to infinity. From a practical point of view, this result implies that the interference constraint cannot be satisfied with equality for N large enough. Hence, we can relax the interference constraint, *i.e.*, the average amount of total interference power at the PBS due to SU transmissions is not a performance limiting criterion any more. Once this happens, the SBS just requires the indices of the SUs for which $g_i \leq g_{K_N:N}$ rather than the actual realizations of the STPB channel gains, which further reduces the amount of feedback required between two networks. Furthermore, our results indicate that the sum-rate scaling behavior of TPIL networks is mainly affected by the distribution of STSB channel power gains rather than that of the STPB channel power gains.

In contrast to TPIL networks, the throughput scaling behavior of IL networks under K-SCG and full-feedback protocols is mainly affected by the distribution of STPB channel power gains rather than that of STSB channel power gains. More specifically, our results for IL networks signify that the secondary network throughput under K-SCG and full-feedback protocols scales according to $\frac{1}{\gamma_g} \log(N)$, where γ_g is a parameter determined from the behavior of the CDF of the STPB channel power gains around the origin. For example, γ_g is equal to 1, m and $\frac{c}{2}$ for Rayleigh (as well as Rician), Nakagami-m and Weibull distributions, respectively. Hence, we conclude that the sum-rate scaling behavior in the IL networks is not affected by K_N. That is, even for $K_N = O(1)$, the sum-rate scaling behavior of an IL network under K-SCG and full-feedback protocols will be the same. This implies that the amount of required feedback between the PBS and SBS can be reduced substantially while keeping the same scaling behavior with that under the full-feedback protocol.

Finally, our results for IPIL networks indicate that the secondary network throughput under both K-SCG and full-feedback protocols scales according to $\min\left(1, \frac{1}{\gamma_g}\right) \log(N)$. Similar to IL networks, K-SCG feedback protocol achieves the same scaling behavior as the full-feedback protocol does even for $K_N = O(1)$, which again results in a substantial amount of feedback reduction at the SBS. The throughput scaling behavior of IPIL networks under K-SCG and full-feedback protocols is mainly affected by the distribution of STPB channel power gains rather than that of STSB channel gains. Our results are summarized in Table I.

---

[1] c is the Weibull fading parameter.

TABLE I
THROUGHPUT SCALING BEHAVIOR OF K-SCG AND FULL-FEEDBACK PROTOCOLS FOR DIFFERENT NETWORK MODELS

Network Model	Feedback Protocol	
	K-SCG	Full
Total-Power-And-Interference-Limited	$\lim_{N\to\infty} \frac{R_N}{\log(\log(K_N))}$[a] $= \frac{1}{n_h}$[b]	$\lim_{N\to\infty} \frac{R_N}{\log(\log(N))} = \frac{1}{n_h}$
Interference-Limited	$\lim_{N\to\infty} \frac{R_N}{\log(N)} = \frac{1}{\gamma_g}$[c]	$\lim_{N\to\infty} \frac{R_N}{\log(N)} = \frac{1}{\gamma_g}$
Individual-Power-And-Interference-Limited	$\lim_{N\to\infty} \frac{R_N}{\log(N)} = \min\left(1, \frac{1}{\gamma_g}\right)$	$\lim_{N\to\infty} \frac{R_N}{\log(N)} = \min\left(1, \frac{1}{\gamma_g}\right)$

[a] R_N is the secondary network sum-rate.
[b] n_h is parameter determined from the asymptotic tail behavior of the CDF of STSB channel power gains.
[c] γ_g is a parameter determined from the behavior of the CDF of STPB channel power gains around the origin.

C. Related Work

Jointly optimal power allocation and spectrum sharing in a cognitive radio setup with single SU has been extensively studied in the literature under different quality-of-service (QoS) criteria such as SU's outage probability and ergodic capacity, and under different constraints on transmit powers of SU and interference power at the primary receiver such as peak or average power and interference constraints [6], [11], [13]. These papers show that optimal resource allocation and interference management tasks in cognitive radio networks highly depends on the knowledge of secondary-transmitter-primary-receiver channel gain. Optimal power allocation and spectrum sharing policy maximizing sum-rate in CMACs as well as cognitive broadcast channels (CBCs) under various transmit power and interference constraints has also been recently studied in [7]. It has been shown that the optimal power allocation for a CMAC under average transmit power and average interference constraints for continuous fading distributions is to schedule the SU with the best joint power and interference channel state. This result implies that the SBS requires interference channel gains of all SUs to perform the optimal scheduling and power allocation. Similar to these previous works, our performance measure in this paper is also the secondary network sum-rate capacity under the jointly optimal power control and spectrum sharing policy. Different from them, we focus on the feedback limited communication environments in which STPB channel states are available only for a subset of SUs at the SBS, and obtain tight sum-rate capacity scaling laws under such feedback limitations.

Capacity scaling laws in CMACs under the complete knowledge of STPB channel gains has also been investigated in the literature, *e.g.,* see [8], [9] and [10], under various type of constraints on the transmit powers of SUs. The authors in [8] studied the capacity scaling laws for a multiple access secondary network for Rayleigh fading channels under joint peak transmit power and peak interference power constraints. They established logarithmic and double-logarithmic secondary network capacity scaling behavior under some approximations. Zhang *et al.* [9] extended these results to CMACs, CBCs, and cognitive parallel access channels. In [10], the authors studied throughput scaling behavior of IL and TPIL CMACs under full primary-secondary feedback assumption when transmit powers of SUs are optimally allocated. For specific communication environments, *i.e.*, specific fading channel models for STSB and STPB channel gains, they showed that the secondary network sum-rate scales double logarithmically and logarithmically in TPIL and IL networks, respectively. These previous works did not consider feedback limited communication environments, and assumed very specific fading distributions to derive the stated sum-rate capacity scaling laws.

Other related work includes secondary network capacity scaling in a multi-band setup such as [14] and [15]. In [14], the authors studied the multiuser and multi-spectrum diversity gains for a cognitive broadcast network sharing multiple orthogonal frequency bands with a primary network. Assuming Rayleigh fading channels, they analytically derived capacity expressions for the secondary network when the transmit power at each band is limited by a constraint on the peak interference power that the SBS can cause to the primary network. In [15], the authors considered N secondary transmitter-receiver pairs sharing M frequency bands with a primary network. Under the optimum matching of M SUs with M primary network frequency bands, they obtained a double-logarithmic scaling law for the secondary network capacity for Rayleigh fading channels. Although the problem formulation in the current paper is different than that in these previous works, similar techniques as in [22] are used to derive capacity scaling laws. We believe some parts of our analysis are expected to find greater applicability to extend sum-rate capacity scaling laws obtained for the dual broadcast channels with multiple transmission bands beyond Rayleigh fading communication environments.

Finally, this work is also partially related to the cooperative multiple access channels (CO-MACs) in which ideal (error-free and infinite-capacity) backhaul links were originally considered to convey the received signal from each base-station to a remote central processor that performs joint data decoding. Effect of finite-capacity backhaul links on the capacity of CO-MACs has been studied in the literature, and different multi-cell processing protocols has been proposed to cope with the backhaul link resource limitations, *e.g.*, see [17], [18] and references therein. From an engineering point of view, cognitive radio network planning task, *e.g.*, design of primary-secondary backhaul links and efficient primary-secondary feedback protocols, highly depends on the knowledge of the secondary network capacity limitations under resource limited primary-secondary backhaul links. However, it should be noted that the problem here is fundamentally different from CO-MACs in that SBS and PBS separately perform the signal decoding, and the backhaul link is only used to convey STPB channel gains to the SBS rather than the PBS received signal.

D. A Note on Notation and Paper Organization

When we write $p(x) = O\left(q(x)\right)$ and $p(x) = o\left(q(x)\right)$ for two positive functions $p(x)$ and $q(x)$, we mean $\limsup_{x\rightarrow\infty} \frac{p(x)}{q(x)} < \infty$ and $\lim_{x\rightarrow\infty} \frac{p(x)}{q(x)} = 0$, respectively. By $p(x) = \Theta\left(q(x)\right)$, we mean $\limsup_{\rightarrow\infty} \frac{p(x)}{q(x)} < \infty$ $\liminf_{x\rightarrow\infty} \frac{p(x)}{q(x)} > 0$.

As is standard in the literature [19], when we say a wireless channel is Rayleigh fading channel, we mean the channel magnitude gain is Rayleigh distributed, or equivalently the channel power gain is exponentially distributed. By a Rician-K_f fading channel, we mean the channel magnitude gain is Rician distributed with a Rician factor K_f. For a Rician-K_f fading channel, the channel power gain is non-central chi-square distributed with two degrees of freedom [20]. When we say a wireless channel is Nakagami-m distributed, we mean the channel magnitude gain is Nakagami distributed with a Nakagami factor $m \geq 0.5$. For a Nakagami-m fading channel, the channel power gain is Gamma distributed. By a Weibull fading channel, we mean the channel magnitude gain is Weibull distributed with parameter $c > 0$. We refer the reader to [19], [20] and [21] for more details about fading distributions.

The rest of the paper is organized as follows. Section II describes the system model and network configuration along with our modeling assumptions. Section III derives and compares the secondary network sum-rate scaling under K-SCG and full feedback protocols, discusses the effect of fading channel parameters on the scaling laws, provides various insights into the derived throughput scaling laws, and illustrates the accuracy of our results by means of numerical study for cognitive radio networks with finitely many SUs. Section IV concludes the paper. All proofs are relegated to the Appendix.

II. SYSTEM MODEL

Consider an underlay cognitive multiple access network as described above: N SUs transmit data to an SBS and interfere with the signal reception at a PBS. Let h_i and g_i represent the fading power gains for the ith STSB and STPB links, respectively. The classical ergodic block fading model [16] is assumed to hold to model variations in channel states for all STPB and STSB links. Further, we assume that h_i's and g_i's are i.i.d. random variables, and the random vectors $\boldsymbol{h} = [h_1, h_2, \dots, h_N]^\top$ and $\boldsymbol{g} = [g_1, g_2, \dots, g_N]^\top$ are also independent. The communication set-up is represented in Fig. 1 pictorially.

Definition 2.1: We say that the cumulative distribution function (CDF) of a random variable X, denoted by $F(x)$, belongs to the class $\mathcal{C}$-distributions if it satisfies the following properties:

- $F(x)$ is continuous.
- $F(x)$ has a positive support, *i.e.,* $F(x) = 0$ for $x \leq 0$.
- $F(x)$ is strictly increasing, *i.e.,* $F(x_1) < F(x_2)$ for $0 < x_1 < x_2$.
- The tail of $F(x)$ decays to zero *double exponentially*, *i.e.,* there exist constants $\alpha > 0$, $\beta > 0$, $n > 0$, $l \in \mathbb{R}$ and a slowly varying function $H(x)$ satisfying $H(x) = o(x^n)$ such that

$$\lim_{x \to \infty} \frac{1 - F(x)}{\alpha x^l \mathrm{e}^{(-\beta x^n + H(x))}} = 1. \tag{1}$$

- $F(x)$ varies *regularly* around the origin, *i.e.,* there exist constants $\eta > 0$ and $\gamma > 0$ such that

$$\lim_{x \downarrow 0} \frac{F(x)}{\eta x^\gamma} = 1. \tag{2}$$

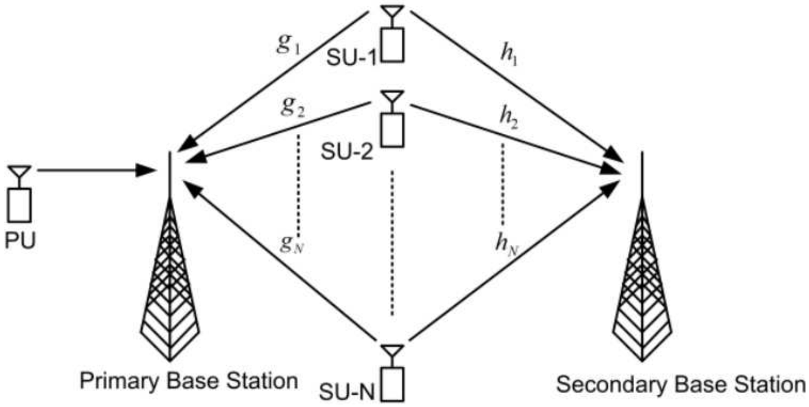

Fig. 1. N SUs forming a multiple access channel to the SBS and interfering with signal reception at the PBS.

TABLE II
COMMON FADING CHANNEL MODELS AND THEIR PARAMETERS

Channel Model	Parameters						
	α	l	β	n	$h(x)$	η	γ
Rayleigh	1	0	1	1	0	1	1
Rician	$\frac{1}{2\sqrt{\pi}\mathrm{e}^{K_f}\sqrt[4]{K_f(K_f+1)}}$	$-\frac{1}{4}$	K_f+1	1	$2\sqrt{K_f\left(K_f+1\right)x}$	$\frac{K_f+1}{\mathrm{e}^{K_f}}$	1
Nakagami-m	$\frac{m^{m-1}}{\Gamma(m)}$	$m-1$	m	1	0	$\frac{m^{m-1}}{\Gamma(m)}$	m
Weibull	1	0	$\Gamma^{\frac{c}{2}}\left(1+\frac{2}{c}\right)$	$\frac{c}{2}$	0	$\Gamma^{\frac{c}{2}}\left(1+\frac{2}{c}\right)$	$\frac{c}{2}$

In this paper, we consider fading power gains with CDFs belonging to the class $\mathcal{C}$-distributions. The parameters characterizing the behavior of the distribution of fading power gains around zero and infinity are illustrated in Table II for the commonly used fading models in the literature. To avoid any confusion, we represent these parameters with subscript h for STSB channel gains and with subscript g for STPB channel gains, *e.g.*, η_g or η_h, in the remainder of the paper.

Different constraints on the transmit powers of SUs and PSFL are considered. In each case, we study the throughput scaling behavior of the secondary network when the transmit powers of SUs are optimally allocated subject to these constraints. We define a power allocation policy $\boldsymbol{P}\left(\boldsymbol{h},\boldsymbol{g}\right)=\left[P_1\left(\boldsymbol{h},\boldsymbol{g}\right),\cdots,P_N\left(\boldsymbol{h},\boldsymbol{g}\right)\right]^\top$ as a mapping from $\mathbb{R}^{2N}$ to $\mathbb{R}^N$ in which $P_i\left(\boldsymbol{h},\boldsymbol{g}\right)$ is the transmit power of SU-i. The sum-rate scaling behavior of the secondary networks are studied under different combinations of the following constraints:

$$\text{Set of Constraints Considered:} \begin{cases} \mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\mathbf{1}^\top \boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})\right] \leq P_{\text{ave}}, & \text{(3a)} \\ \mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[P_i(\boldsymbol{h},\boldsymbol{g})\right] \leq P_{\text{ave}} \quad 1 \leq i \leq N, & \text{(3b)} \\ \mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\boldsymbol{g}^\top \boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})\right] \leq Q_{\text{ave}}, & \text{(3c)} \\ P_i(\boldsymbol{h},\boldsymbol{g})\, 1_{\left\{g_i > g_{K_N:N}\right\}} = 0 \quad 1 \leq i \leq N, & \text{(3d)} \\ P_i(\boldsymbol{h},\boldsymbol{g}) \geq 0, & \text{(3e)} \end{cases}$$

where (3a), (3b) and (3c) are average total power, average individual power and average total interference power constrains, respectively. (3d) is a constraint to guarantee that a SU is allowed to transmit only if its STPB channel gain is available at the SBS. (3d) will be called the *feedback constraint* in the remainder of the paper.

A. TPIL Networks:

In TPIL networks, we examine the secondary network throughput scaling behavior in two communication scenarios (CoSs) of interest: $\text{CoS}^{\text{F}}_{\text{TPIL}}$ and $\text{CoS}^{K}_{\text{TPIL}}$. In $\text{CoS}^{\text{F}}_{\text{TPIL}}$, transmit powers of SUs are limited by an average total power constraint and an average total interference power constraint without any restriction on the amount of feedback information to be exchanged between the PBS and SBS. Hence, transmit powers of SUs are allocated according to the solution of the following optimization problem [2]:

$$\begin{array}{l} \max\limits_{\boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})} \mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\log\left(1 + \boldsymbol{h}^\top \boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})\right)\right] \\ \text{subject to : (3a), (3c) and (3e)} \end{array}. \tag{4}$$

The solution to (4) was derived in [7], [10] as

$$P^\star_{i,N}(\boldsymbol{h},\boldsymbol{g}) = \begin{cases} \left(\frac{1}{\lambda_N + \mu_N g_i} - \frac{1}{h_i}\right)^+ & \text{if } i = \arg\max\limits_{1 \leq j \leq N} \frac{h_j}{\lambda_N + \mu_N g_j} \\ 0 & \text{otherwise} \end{cases}. \tag{5}$$

This result intuitively indicates that the jointly optimal spectrum sharing and power-control policy maximizing information theoretic sum-rate capacity of a CMAC network under the full-feedback protocol with average total transmit and interference power constraints for continuous fading distributions is to schedule the SU with the best joint power and interference channel state summarized by the random variable $X^\star_N(\lambda_N, \mu_N) = \max_{1 \leq i \leq N} \frac{h_i}{\lambda_N + \mu_N g_i}$ according to a power allocation policy in the form of a water-filling algorithm with changing water levels. Let $R^{\text{F}}_{\text{TPIL}}(N)$ be the sum-rate of the secondary network for the *all* feedback scenario. Then, it follows directly that

$$R^{\text{F}}_{\text{TPIL}}(N) = \mathsf{E}\left[\log\left(X^\star_N(\lambda_N, \mu_N)\right) 1_{\left\{X^\star_N(\lambda_N,\mu_N) \geq 1\right\}}\right], \tag{6}$$

---

[2] Here, similar to [7], we assume that either the SBS can cancel primary interference, or the background noise at the SBS includes primary interference, and the resulting noise is modeled as a circularly symmetric complex Gaussian random variable with zero mean and unit variance.

where λ_N and μ_N are Lagrange multipliers associated with the average total transmit and interference power constraints, respectively.

On the other hand, transmit powers of SUs in $\text{CoS}_{\text{TPIL}}^{K}$ are also limited by the extra feedback constraint in (3d), besides the average total transmit and interference power constraints above. Hence, transmit powers of SUs in this case are allocated according to the solution of the following optimization problem:

$$\begin{array}{l} \max\limits_{\boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})} \mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\log\left(1+\boldsymbol{h}^{\top}\boldsymbol{P}\left(\boldsymbol{h},\boldsymbol{g}\right)\right)\right] \\ \text{subject to : (3a), (3c), (3d), and (3e)} \end{array} . \tag{7}$$

Lemma 1: Let $\pi(j)$ be a mapping from $\{1,\cdots,K_N\}$ to $\{1,\cdots,N\}$ such that

$$\pi(j)=i \quad \text{if} \quad g_i = g_{j:N}.$$

Then, the solution for (7) is given by

$$P_{i,K_N}^{\star}\left(\boldsymbol{h},\boldsymbol{g}\right)=\begin{cases} \left(\frac{1}{\lambda_N+\mu_N g_i}-\frac{1}{h_i}\right)^{+} & \text{if } i=\pi\left(\arg\max\limits_{1\leq j\leq K_N}\frac{h_{\pi(j)}}{\lambda_N+\mu_N g_{\pi(j)}}\right) \\ 0 & \text{otherwise} \end{cases} . \tag{8}$$

Proof: Follows directly by inspecting the structure of the solution given for (4) in (5). ■

Hence, the sum-rate in $\text{CoS}_{\text{TPIL}}^{K}$ scenario is given by

$$R_{\text{TPIL}}^{K}\left(K_N\right)=\mathsf{E}\left[\log(X_{K_N}^{\star}\left(\lambda_N,\mu_N\right))1_{\left\{X_{K_N}^{\star}\left(\lambda_N,\mu_N\right)\geq 1\right\}}\right], \tag{9}$$

where $X_{K_N}^{\star}\left(\lambda_N,\mu_N\right)=\max_{1\leq j\leq K_N}\frac{h_{\pi(j)}}{\lambda_N+\mu_N g_{\pi(j)}}$. This expression makes it clear that the jointly optimal spectrum sharing and power-control policy maximizing information theoretic sum-rate capacity of a CMAC network under the K-SCG feedback protocol with average total transmit and interference power constraints for continuous fading distributions is to schedule the SU with the best joint power and interference channel state among the ones whose STPB channel states are fed back to the SBS.

B. IL Networks:

We study throughput scaling behavior of IL networks under two CoSs of interest: $\text{CoS}_{\text{IL}}^{\text{F}}$ and $\text{CoS}_{\text{IL}}^{K}$. In $\text{CoS}_{\text{IL}}^{\text{F}}$, transmit powers of SUs are limited only by an average total interference power constraint. In this case, the secondary network sum-rate is given by:

$$R_{\text{IL}}^{\text{F}}\left(N\right)=\mathsf{E}\left[\log\left(X_N^{\star}\left(0,\mu_N\right)\right)1_{\left\{X_N^{\star}\left(0,\mu_N\right)\geq 1\right\}}\right]. \tag{10}$$

In addition to the average total interference power constraint, transmit powers of SUs are also limited by the feedback constraint (3d) in $\text{CoS}_{\text{IL}}^{K}$. The secondary network sum-rate in $\text{CoS}_{\text{IL}}^{K}$ is given by:

$$R_{\text{IL}}^{K}\left(K_N\right)=\mathsf{E}\left[\log\left(X_{K_N}^{\star}\left(0,\mu_N\right)\right)1_{\left\{X_{K_N}^{\star}\left(0,\mu_N\right)\geq 1\right\}}\right]. \tag{11}$$

C. IPIL Networks:

Similar to the above cases, we investigate the secondary network throughput scaling behavior of IPIL networks under two CoSs of interest: $\text{CoS}_{\text{IPIL}}^{\text{F}}$ and $\text{CoS}_{\text{IPIL}}^{K}$. In $\text{CoS}_{\text{IPIL}}^{\text{F}}$, transmit powers of SUs are limited by individual average transmit power constraints and an average total interference power constraint. Hence, transmit powers of SUs are allocated according to the solution of the following optimization problem:

$$\begin{array}{l}\max\limits_{\boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})}\mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\log\left(1+\boldsymbol{h}^{\top}\boldsymbol{P}\left(\boldsymbol{h},\boldsymbol{g}\right)\right)\right]\\ \text{subject to : (3b), (3c) and (3e)}\end{array}. \tag{12}$$

The sum-rate in $\text{CoS}_{\text{IPIL}}^{\text{F}}$ is given by:

$$R_{\text{IPIL}}^{\text{F}}\left(N\right)=\mathsf{E}\left[\log\left(X_{N}^{\star}\left(\lambda_N,\mu_N\right)\right)1_{\left\{X_{N}^{\star}\left(\lambda_N,\mu_N\right)\geq 1\right\}}\right]. \tag{13}$$

In $\text{CoS}_{\text{IPIL}}^{K}$, in addition to the individual average transmit power and average total interference power constraints, transmit powers of SUs are also limited by the feedback constraint in (3d). Hence, the transmit powers of SUs are allocated according to the solution of the following optimization problem:

$$\begin{array}{l}\max\limits_{\boldsymbol{P}(\boldsymbol{h},\boldsymbol{g})}\mathsf{E}_{\boldsymbol{h},\boldsymbol{g}}\left[\log\left(1+\boldsymbol{h}^{\top}\boldsymbol{P}\left(\boldsymbol{h},\boldsymbol{g}\right)\right)\right]\\ \text{subject to : (3b), (3c), (3d) and (3e)}\end{array}. \tag{14}$$

The sum-rate in $\text{CoS}_{\text{IPIL}}^{K}$ is given by:

$$R_{\text{IPIL}}^{K}\left(K_N\right)=\mathsf{E}\left[\log\left(X_{K_N}^{\star}\left(\lambda_N,\mu_N\right)\right)1_{\left\{X_{K_N}^{\star}\left(\lambda_N,\mu_N\right)\geq 1\right\}}\right]. \tag{15}$$

The different communication scenarios studied in this paper are summarized in Table III.

III. RESULTS AND DISCUSSIONS

In this section, we state the main asymptotic sum-rate scaling results of the paper along with numerical analysis illustrating them for finite networks. We also discuss various insights about the derived sum-rate scaling results. The proofs are relegated to the appendices for the sake of fluency of the paper. Our first result establishes the scaling behavior for $R_{\text{TPIL}}^{\text{F}}\left(N\right)$ and $R_{\text{TPIL}}^{K}\left(K_N\right)$.

Theorem 1: Let K_N grow to infinity at a rate $K_N=o\left(N\right)$. Then, the sum-rates $R_{\text{TPIL}}^{\text{F}}\left(N\right)$ and $R_{\text{TPIL}}^{K}\left(K_N\right)$ under $\text{CoS}_{\text{TPIL}}^{\text{F}}$ and $\text{CoS}_{\text{TPIL}}^{K}$, respectively, scale according to

$$\lim_{N\to\infty}\frac{R_{\text{TPIL}}^{K}\left(K_N\right)}{\log\left(\log\left(K_N\right)\right)}=\lim_{N\to\infty}\frac{R_{\text{TPIL}}^{\text{F}}\left(N\right)}{\log\left(\log\left(N\right)\right)}=\frac{1}{n_h}.$$

TABLE III

NETWORK TYPES AND FEEDBACK PROTOCOLS STUDIED FOR DIFFERENT COMMUNICATION SCENARIOS

Communication Scenario	Network Type	Feedback Protocol
$\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$	TPIL	Full-Feedback
$\mathrm{CoS}_{\mathrm{TPIL}}^{K}$	TPIL	K-SCG
$\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$	IL	Full-Feedback
$\mathrm{CoS}_{\mathrm{IL}}^{K}$	IL	K-SCG
$\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$	IPIL	Full-Feedback
$\mathrm{CoS}_{\mathrm{IPIL}}^{K}$	IPIL	K-SCG

Proof: Please see Appendix B. ■

In Appendix B, we give a detailed proof for Theorem 1 for $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$, and only the key proof ideas for $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ are illustrated to avoid repetition. Theorem 1 indicates that the secondary network throughput scales double-logarithmically under $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$ with N and K_N, respectively, when distributions of STPB and STSB channel power gains belong to class $\mathcal{C}$-distributions. Hence, for $K_N = N^{\delta}$ and $\delta \in (0,1)$, the secondary network throughput scaling behavior under $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$ are the same. Since δ can be chosen arbitrarily close to zero, this result implies that under K-SCG feedback protocol, the amount of feedback in the PSFL can be dramatically reduced while the secondary network still achieves the same scaling behavior as the one achieved by the full-feedback protocol.

The dependence of multiuser diversity gains (MDGs) in $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$ on K_N indicates that the STSB channel gains are the major source of MDGs in TPIL networks. This is mainly because the Lagrange multipliers λ_N cannot be made arbitrarily close to zero (see Lemma 5 in appendix B) in this case, and as a result, the asymptotic behavior of $\max_{1 \leq i \leq K_N} \frac{h_{\pi(i)}}{\lambda_N + \mu_N g_{\pi(i)}}$ is primarily governed by the distribution of STSB channel gains. Larger K_N implies that more STPB channel gains are available at the SBS, and we observe a corresponding increase in the MDG. Moreover, the Theorem 1 reveals that the secondary network sum-rate scaling behavior under $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$ is controlled by a pre-log factor of $\frac{1}{n_h}$. To put it another way, the available degrees of freedom for the cognitive multiple access channel in question reversely depends on the tail decay rate of the CDF of the STSB channel power gains[3]. The pre-log factor is equal to $\frac{2}{c}$ for the Weibull distributed STSB channel gains, and equal to 1 for Rayleigh, Rician and Nakagami-m distributed STSB channel gains.

In Appendix B, we show that the Lagrange multipliers λ_N converge to $\frac{1}{P_{\mathrm{ave}}}$ as N becomes large both in $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$. This finding is helpful to study the second order effects of the average total power constraint P_{ave} on the secondary network throughput under $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$. Based on our analysis in Appendix B, we characterize the second order effects of P_{ave} and other fading parameters on the secondary network throughput under $\text{CoS}_{\text{TPIL}}^{\text{F}}$ for finite number of SUs by bounding $R_{\text{TPIL}}^{\text{F}}(N)$ from above and below as

---

[3] Note that for distribution functions belonging to the class $\mathcal{C}$-distributions, n mainly controls their tail decay rates (see Definition 2.1).

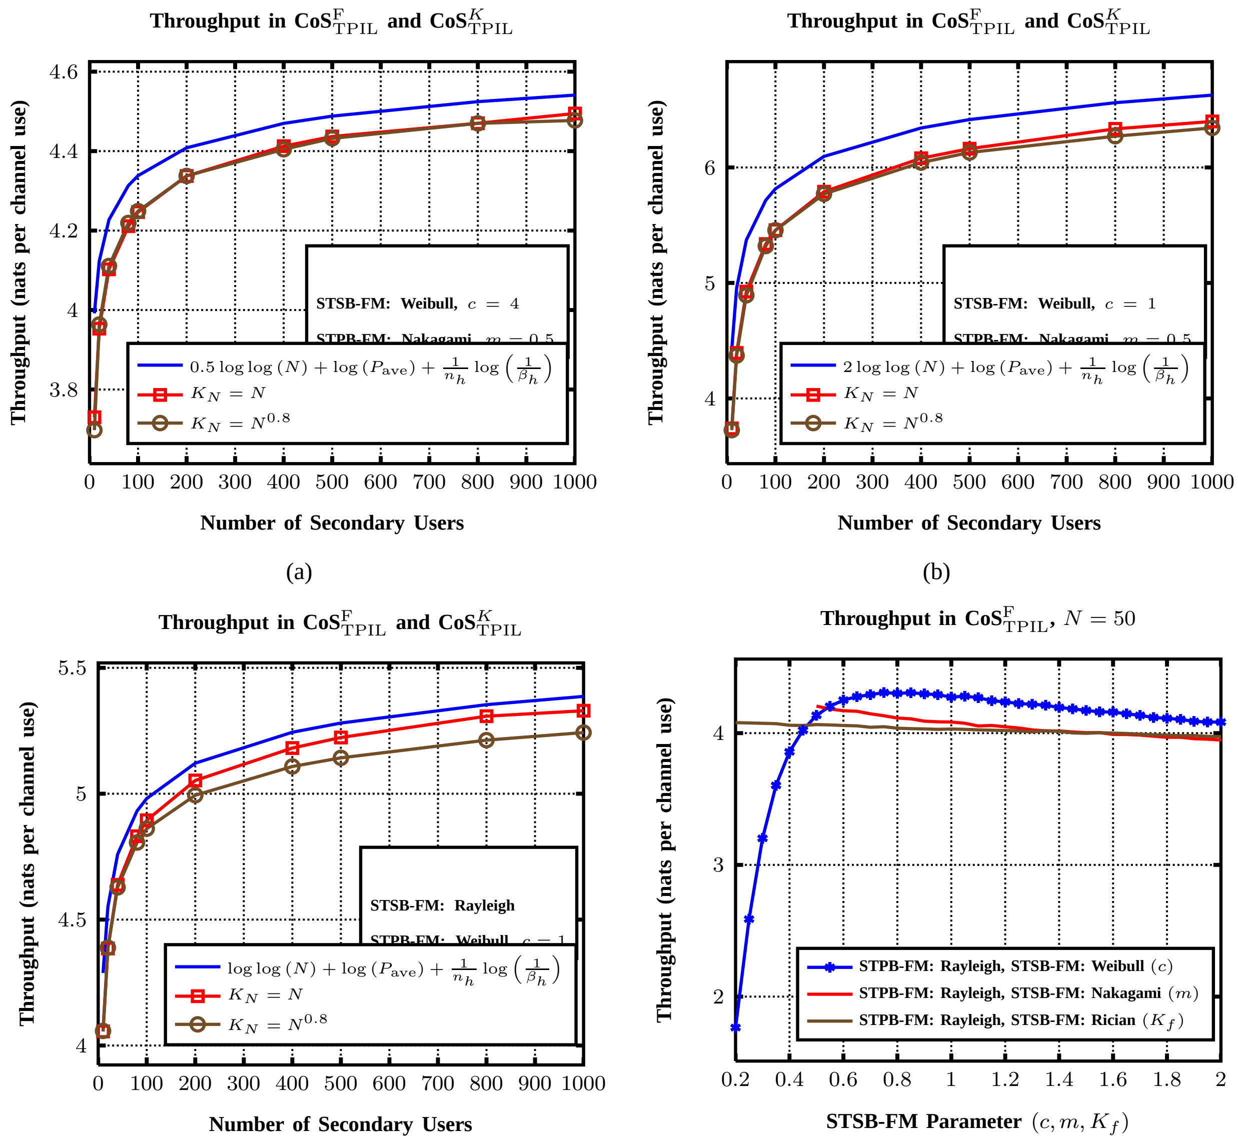
$$(1-\epsilon)\frac{1}{n_h}\log\log(N)+\log(P_{\text{ave}})+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)+O(1)\leq R_{\text{TPIL}}^{\text{F}}(N)\leq$$
$$(1+\epsilon)\frac{1}{n_h}\log\log(N)+\log(P_{\text{ave}})+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)+O(1), \tag{16}$$

for all $\epsilon>0$ and N large enough (*i.e.,* see (34)). Therefore, an increase in P_{ave} results in a corresponding logarithmic increase in $R_{\text{TPIL}}^{\text{F}}(N)$, implying that P_{ave} has a logarithmic effect on $R_{\text{TPIL}}^{\text{F}}(N)$. For a given a fading model for STSB channel gains, the constant term $\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)$ in (16) can be thought of being the second order effect of the fading model on $R_{\text{TPIL}}^{\text{F}}(N)$ for finitely many SUs. $\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)$ is equal to $\log\left(\frac{1}{K_f+1}\right)$ for the Rician distributed STSB channel gains, and equal to $\log\left(\frac{1}{m}\right)$ for the Nakagami-m distributed STSB channel gains. This implies that for a fixed number of SUs, as the Rician factor K_f or the Nakagami-m parameter m increases, we observe a logarithmic reduction in the secondary network throughput. The reason for this behavior is that STSB channel gains become more deterministic as K_f or m increases, and as a result, the MDG drops since it depends on the dynamic range of the CDF of the STSB channel gains.

For the Weibull distributed STSB channel gains, $\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)$ is equal to $\log\left(\frac{1}{\Gamma\left(1+\frac{2}{c}\right)}\right)$, which first increases and then decreases as the Weibull fading parameter c grows large. This behavior can be explained as follows. For small values of c, the Weibull distribution is concentrated around zero, *i.e.,* it is almost deterministic, whereas its dynamic range expands as c increases. Thus, the second order term $\log\left(\frac{1}{\Gamma\left(1+\frac{2}{c}\right)}\right)$ in sum-rate expression increases as c increases from zero. On the other hand, as c becomes large, after a certain point, the Weibull distribution starts to concentrate around one, *i.e.,* it becomes deterministic again, and as a result the second order term $\log\left(\frac{1}{\Gamma\left(1+\frac{2}{c}\right)}\right)$ drops again. Finally, we note that P_{ave} and STSB fading distribution parameters have the similar logarithmic second order effects on the secondary network throughput under $\text{CoS}_{\text{TPIL}}^{K}$ (*i.e.,* see (33)).

Fig. 2(a)-(c) demonstrate the sum-rate scaling behavior of the secondary network under $\text{CoS}_{\text{TPIL}}^{\text{F}}$ and $\text{CoS}_{\text{TPIL}}^{K}$ as a function of the number of SUs for different STSB-fading models (STSB-FMs) and STPB-fading models (STPB-FMs). P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively. Similar qualitative behavior continues to hold for other values of P_{ave} and Q_{ave}. In Fig. 2(a)-(c), the curves with $K_N=N$ represent the secondary network sum-rate under $\text{CoS}_{\text{TPIL}}^{\text{F}}$, and the curves with $K_N=N^{0.8}$ represent the secondary network sum-rate under $\text{CoS}_{\text{TPIL}}^{K}$.

In Fig. 2(a) and Fig. 2(b), STSB and STPB channel gains are distributed according to Weibull and Nakagami-m fading models, respectively. Weibull fading parameter, c, is set to 4 in Fig. 2(a) and to 1 in Fig. 2(b). In both figures, Nakagami fading parameter m is set to 0.5. As Fig. 2(a) and Fig. 2(b) demonstrate, the sum-rate of the secondary network under $\text{CoS}_{\text{TPIL}}^{\text{F}}$ and $\text{CoS}_{\text{TPIL}}^{K}$ scales according to $\frac{2}{c}\log\log(N)$ when STSB channel gains are Weibull distributed. That is, the scaling behavior is $0.5\log\log(N)$ for $c=4$ and $2\log\log(N)$ for $c=1$, which is in accordance with the MDGs predicted by Theorem 1. Similar qualitative behavior continues to hold for other values of m and c.



(a) (b)

(c) (d)

Fig. 2. Secondary network throughput scaling under CoS$^{\mathrm{F}}_{\mathrm{TPIL}}$ ($K_N = N$) and CoS$^{K}_{\mathrm{TPIL}}$ ($K_N = N^{0.8}$) for different communication environments (a)-(c). Secondary network throughput under CoS$^{\mathrm{F}}_{\mathrm{TPIL}}$ as a function of the STSB-FM parameter for $N = 50$ (d). P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively.

In Fig. 2(c), the Rayleigh fading model is used to model STSB channel variations, and the Weibull fading model is used to model STPB channel variations. The Weibull fading parameter c is set to 1. As Fig. 2(c) shows, secondary network throughput scales according to $\log\log(N)$ when STSB channel gains are Rayleigh distributed as predicted by Theorem 1. Similar qualitative behavior continues to hold for other values of c. In particular, closeness of simulated data rates and $\frac{1}{n_h}\log\log(N) + \log(P_{\mathrm{ave}}) + \frac{1}{n_h}\log\left(\frac{1}{\beta_h}\right)$ curves in Fig. 2 further indicates the logarithmic effect of P_{ave} as well as other second order effects of the STPB fading parameters on the secondary network throughput under CoS$^{\mathrm{F}}_{\mathrm{TPIL}}$ and CoS$^{K}_{\mathrm{TPIL}}$. Furthermore, as Fig. 2(a)-(c) show, throughput loss due to implementing the K-SCG feedback protocol is negligible, which indicates that the K-SCG feedback protocol is an effective primary-secondary feedback reduction policy even for finitely many SUs.

Fig. 2(d) shows the second order effects of the fading parameters on the secondary network sum-rate under $\text{CoS}^{\text{F}}_{\text{TPIL}}$ for $N = 50$. In Fig. 2(d), STPB channel gains are Rayleigh distributed, whereas Weibull, Nakagami and Rician fading models are considered for STSB channel gains. As the Rician fading parameter K_f or the Nakagami-m fading parameter m becomes large, the STSB channel gains become more deterministic, and as a result the secondary network throughput drops as predicted by our discussion above. As the Weibull fading parameter c becomes large, the secondary network throughput first increases and then decreases, which is also in accordance with our discussion above.

Remark 1: In Appendix A, we show that the concentration behavior of the extreme order statistic of an i.i.d. sequence of random variables with the common CDF $F(x)$, which does not have to have a closed form expression, is characterized by the functional inverse of the function $G(x)$ characterizing the tail behavior of $F(x)$, *i.e.*, $\lim_{x\to\infty} G(x)\left(1 - F(x)\right) = 1$. This is the key result used to establish the secondary network sum-rate scaling under different CoSs.

Remark 2: In Appendix B, we show that the sum-rate of a primary multiple access network with a total power constraint $R_{\text{TPL}}(N)$ scales according to $\lim_{N\to\infty} \frac{R_{\text{TPL}}(N)}{\log\log(N)} = \frac{1}{n_h}$ when the CDF of the channel gains belong to the class $\mathcal{C}$-distributions. This result is used to establish the upper bound on the secondary network sum-rate under $\text{CoS}^{\text{F}}_{\text{TPIL}}$.

Our next theorem establishes an important convergence behavior for the total interference power at the PBS under $\text{CoS}^{K}_{\text{TPIL}}$ as the number of SUs grows large.

Theorem 2: Let $\mathcal{I}_{K_N}$ be the secondary network interference power at PBS under $\text{CoS}^{K}_{\text{TPIL}}$. For $K_N = o(N)$, $\lim_{N\to\infty} \mathcal{I}_{K_N} = 0$ almost surely and $\lim_{N\to\infty} \mathsf{E}\left[\mathcal{I}_{K_N}\right] = 0$.

Proof: Please see Appendix C. ■

In Appendix C, we give a detailed proof for the convergence of $\mathcal{I}_{K_N}$ to zero in mean, and then we use this result to conclude the almost sure convergence of $\mathcal{I}_{K_N}$ to zero. These convergence results can be justified by the fact that $g_{K_N:N}$, *i.e.*, the largest STPB channel gain available at the SBS under the K-SCG feedback protocol, converges to zero as N becomes large for $K_N = o(N)$. An important practical consequence of Theorems 1 and 2 is that for $K_N = N^{\delta}$ and $\delta \in (0, 1)$, the secondary network under $\text{CoS}^{K}_{\text{TPIL}}$ achieves the optimal throughput scaling behavior while the interference at the PBS becomes negligible as N grows large. To put it in other words, the secondary network can co-exist with the primary network by *virtually* causing no interference, and yet still achieving the optimal data rates.

It is also important to note that Theorem 2 implies the existence of a constant N_0 such that for all $N \geq N_0$, the average interference power constraint at the PBS cannot be satisfied with equality. Therefore, the Lagrange multipliers associated with the average interference power constraint become zero for all N large enough, *i.e.*, $\mu_N = 0$ for all $N \geq N_0$. As a result, the SBS just requires the index set $I_{K_N} = \{i : i = \pi(j), 1 \leq j \leq K_N\}$ to choose the SU with the best STSB channel gain for the optimum power allocation. From a practical point of view, this phenomenon provides an extra reduction in the total feedback load required to achieve the optimum

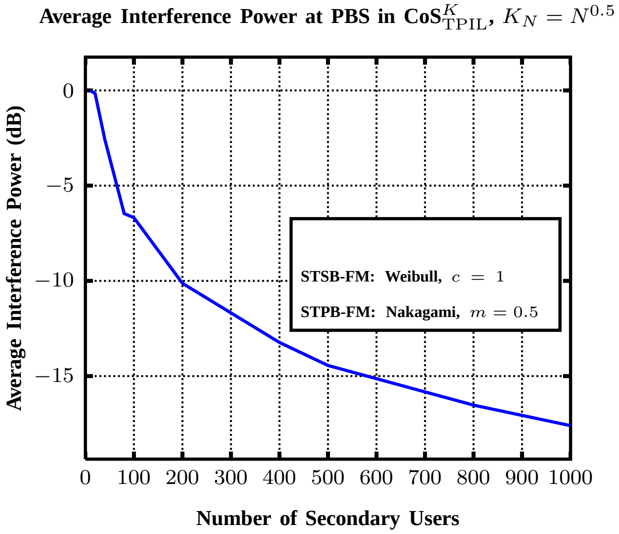


Fig. 3. The change of average interference power at the PBS with N under CoS$^{K}_{\mathrm{TPIL}}$. $K_N = N^{0.5}$. P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively.

throughput scaling for cognitive radio networks.

In Fig. 3, we depict the average interference power at the PBS under CoS$^{K}_{\mathrm{TPIL}}$ for $K_N = N^{0.5}$. P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively. The STSB channel gains are distributed according to the Weibull fading model with $c = 1$, and the STPB channel gains are Nakagami-m distributed with $m = 0.5$. As Fig. 3 shows, the average interference power at the PBS under CoS$^{K}_{\mathrm{TPIL}}$ converges to zero when the number of SUs becomes large, a behavior which was predicted by Theorem 2.

Our next theorem establishes the secondary network scaling behavior under CoS$^{\mathrm{F}}_{\mathrm{IL}}$ and CoS$^{K}_{\mathrm{IL}}$.

Theorem 3: Let $R^{\mathrm{F}}_{\mathrm{IL}}(N)$ and $R^{K}_{\mathrm{IL}}(K_N)$ be the secondary network throughput under CoS$^{\mathrm{F}}_{\mathrm{IL}}$ and CoS$^{K}_{\mathrm{IL}}$ for $0 < K_N \leq N$, respectively. Then,

$$\lim_{N \to \infty} \frac{R^{\mathrm{F}}_{\mathrm{IL}}(N)}{\log(N)} = \lim_{N \to \infty} \frac{R^{K}_{\mathrm{IL}}(K_N)}{\log(N)} = \frac{1}{\gamma_g}.$$

Proof: Please see Appendix D. ■

Theorem 3 establishes the logarithmic scaling behavior for the secondary network sum-rate with N under CoS$^{\mathrm{F}}_{\mathrm{IL}}$ and CoS$^{K}_{\mathrm{IL}}$ when the CDFs of STPB and STSB channel gains belong to the class $\mathcal{C}$-distributions. Theorem 3 also indicates that the secondary network sum-rate scaling behavior under CoS$^{K}_{\mathrm{IL}}$ is independent of the scaling behavior of K_N with N. Hence, the optimal secondary network throughput scaling behavior in CoS$^{K}_{\mathrm{IL}}$ can be attained even with $K_N = O(1)$. This is primarily because the STPB channel gains turn out to be the main source of MDGs in IL networks since $\frac{h_i}{g_i}$ and $\frac{1}{g_i}$ have the similar tail behavior *i.e.*, see Appendix D. Thus, the common CDF of the STPB channel gains characterizes the asymptotic behavior of $\max_i \frac{h_i}{g_i}$. As a result, scheduling the SU with the smallest STPB channel gain for transmission does not change the sum-rate capacity scaling behavior up to a first order. STSB channel gains only have a second order effect on the secondary network sum-rate.

Furthermore, Theorem 3 reveals that the secondary network throughput scaling under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IL}}^{K}$ is controlled by a pre-log factor of $\frac{1}{\gamma_g}$ that is determined from the behavior of the CDF of the STPB channel gains around zero. The pre-log factor is equal to $\frac{2}{c}$, $\frac{1}{m}$ and 1 for the Weibull, Nakagami-m and Rician-K_f distributed STPB channel gains, respectively. The effect of γ_g on $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ and $R_{\mathrm{IL}}^{K}(K_N)$ has an engineering interpretation. For a given fading model for the STPB channel gains, γ_g is a measure for the proximity of the STPB channel power gains to zero. That is, small values of γ_g implies that the STPB channel gains take values close to zero with high probability, and vice versa. Thus, as γ_g increases, the STPB channel gains become large, and consequently SUs reduce their transmission powers in order to meet the average interference power constraint at the PBS. As a result, the secondary network throughput decreases as γ_g becomes large.

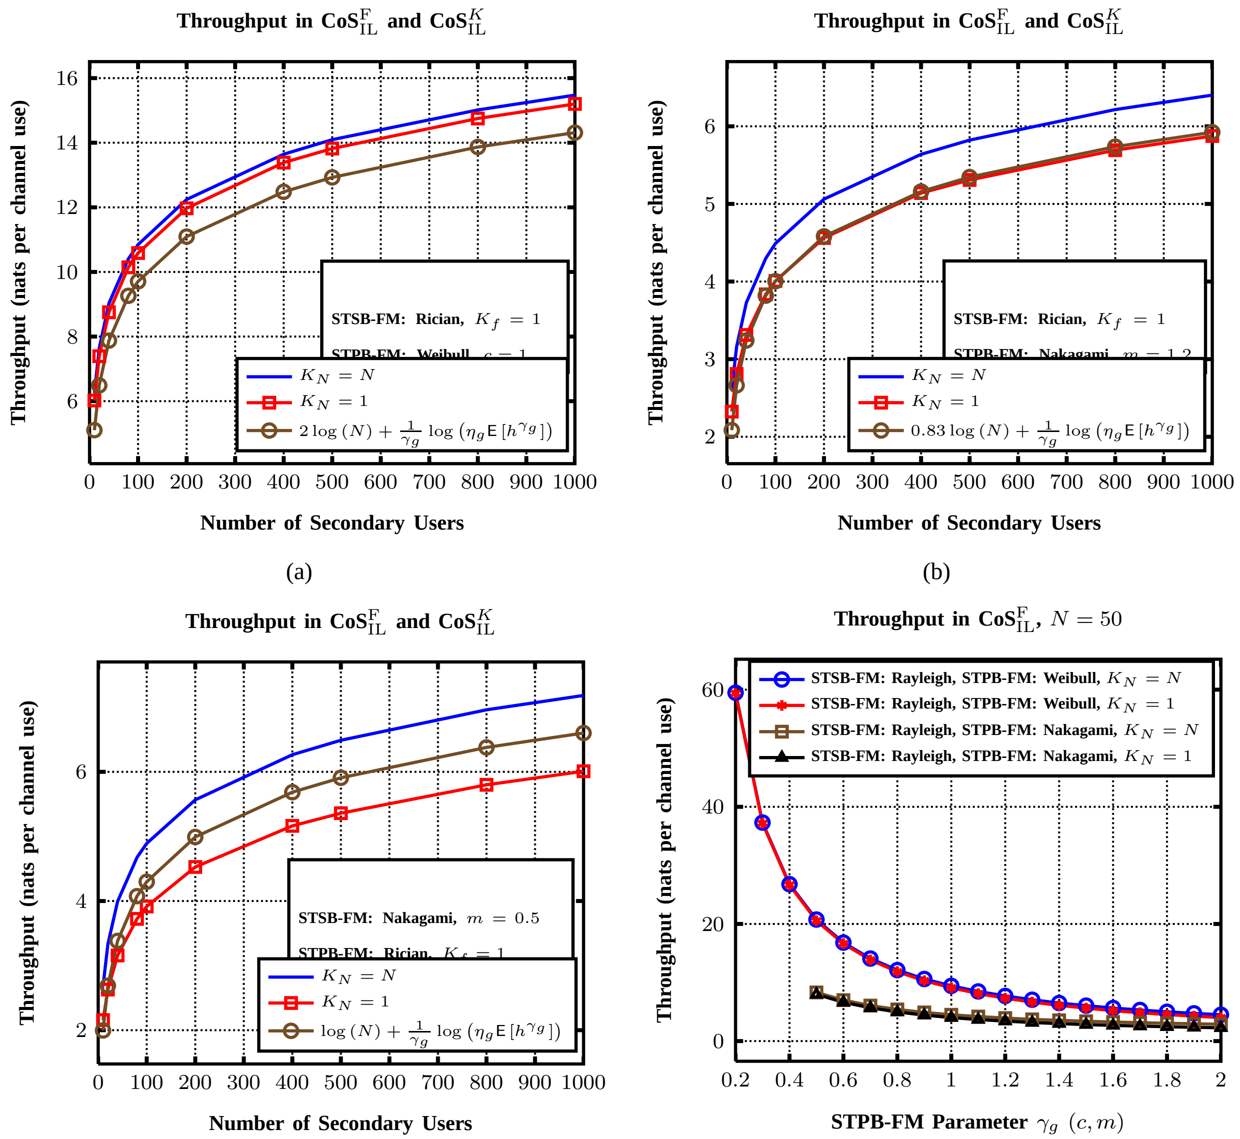
In Appendix D, we show that the Lagrange multipliers μ_N converge to $\frac{1}{Q_{\mathrm{ave}}}$ in $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$. This finding can be used to study the effect of Q_{ave} on the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$. Based on our analysis in Appendix D, we characterize the second order effects of Q_{ave} and fading parameters on the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$ for finite number of SUs by bounding $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ from below and above as

$$(1-\epsilon)\frac{1}{\gamma_g}\log(N)+\log(Q_{\mathrm{ave}})+\frac{1}{\gamma_g}\log\left(\eta_g \mathsf{E}\left[h^{\gamma_g}\right]\right)+O(1)\leq R_{\mathrm{IL}}^{\mathrm{F}}(N)\leq$$
$$(1+\epsilon)\frac{1}{\gamma_g}\log(N)+\log(Q_{\mathrm{ave}})+\frac{1}{\gamma_g}\log\left(\eta_g \mathsf{E}\left[h^{\gamma_g}\right]\right)+O(1) \qquad (17)$$

for all $\epsilon > 0$ and N large enough (*i.e.*, see (45)). Hence, an increase in Q_{ave} leads to a logarithmic increase in $R_{\mathrm{IL}}^{\mathrm{F}}(N)$, impliying that Q_{ave} has a logarithmic effect on $R_{\mathrm{IL}}^{\mathrm{F}}(N)$. Furthermore, the second order effects of the STSB and STPB fading models on $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ can be thought to be embodied in $\frac{1}{\gamma_g}\log\left(\eta_g \mathsf{E}\left[h^{\gamma_g}\right]\right)$, where h is a generic nonnegative random variable with CDF $F_h(x)$. Since $\mathsf{E}\left[h^{\gamma_g}\right]$ term depends on both STPB and STSB fading models, it is not possible to derive general insights about this term for arbitrary combinations of STSB-FMs and STPB-FMs. Hence, we discuss the second order effects of the fading models on $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ when γ_g is one, *i.e.*, Rayleigh or Rician distributed STPB channel gains. In this case, we have $\mathsf{E}\left[h^{\gamma_g}\right]=1$, and (17) suggests that for a fixed number of SUs, $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ is predominantly affected by the parameters of the distribution of the STPB channel gains rather than those of the STSB channel gains. For Rician distributed STPB channel gains, the resulting second order term can be written as $\log\left(\frac{K_f+1}{\mathrm{e}^{K_f}}\right)$, which decreases with K_f. Note that larger K_f implies more power in the line-of-sight component of the Rician fading, which, in turn, implies a larger interference power at the PBS. Hence, SUs decrease their transmission powers to meet the average interference power constraint at the PBS, which results in a reduction in the secondary network throughput.

Remark 3: Operating in the IL scenario does not necessary imply that the average transmit powers of SUs are infinite. It is easy to show that when the distribution of STPB channel gains belong to class $\mathcal{C}$-distributions with $\gamma_g > 1$, the average transmit powers of SUs are finite.

We plot the sum-rate scaling behavior of the secondary network under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IL}}^{K}$ as a function of the number of SUs for different STSB-FMs and STPB-FMs in Figs. 4(a)-(c). In these figures, the curves with



(a)

(b)

(c)

(d)

Fig. 4. Secondary network throughput scaling under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$ ($K_N = N$) and $\mathrm{CoS}_{\mathrm{IL}}^{K}$ ($K_N = 1$) for different communication environments (a)-(c). Secondary network throughput under $\mathrm{CoS}_{\mathrm{TPIL}}^{\mathrm{F}}$ as a function of the STPB-FM parameter γ_g for $N = 50$ in different communication environments (d). Q_{ave} is set to 0dB.

$K_N = N$ represent the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$, and the curves with $K_N = 1$ represent the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IL}}^{K}$. Q_{ave} is set to 0dB. Similar qualitative behavior continues to hold for other values of Q_{ave}. In Fig. 4(a), STSB channel gains are distributed according to the Rician fading model with $K_f = 1$, and STPB channel gains are distributed according to the Weibull fading model with $c = 1$.

Fig. 4(a) shows that the secondary network sum-rate scales according to $\frac{2}{c}\log(N)$ when STPB channel gains are Weibull distributed; a behavior which was predicted by Theorem 3. In Fig. 4(b), STSB channel gains are distributed according to the Rician fading model with $K_f = 1$, and STPB channel gains are distributed according to the Nakagami-m fading model with $m = 1.2$. Fig. 4(b) reveals that the secondary network sum-rate scales according to $\frac{1}{m}\log(N)$ when STPB channel gains are Nakagami-m distributed, which is in accordance with

Theorem 3. In Fig. 4(c), STSB channel gains are distributed according to the Nakagami-m fading model with $m = 0.5$, and STPB channel gains are distributed according to the Rician fading model with $K_f = 1$. As Fig. 4(c) shows, the secondary network sum-rate scales according to $\log(N)$ when STPB channel gains are distributed according to the Rician fading model as predicted by Theorem 3. Fig. 4(a)-(c) demonstrate that the sum-rate loss due to implementing the K-SCG feedback protocol is within one nats per channel use when compared to the full-feedback protocol, which signifies that the K-SCG feedback protocol is an effective primary-secondary feedback reduction policy for interference limited cognitive radio networks.

Fig. 4(d) depicts the dependence of the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IL}}^{K}$ on γ_g in a CMAC with $N = 50$. In this figure, the curves with $K_N = N$ represent the secondary network throughput under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$, and the curves with $K_N = 1$ represent the secondary network throughput under $\mathrm{CoS}_{\mathrm{IL}}^{K}$. STSB channel gains are Rayleigh distributed, and STPB channel gains are Weibull and Nakagami-m distributed. In Fig. 4(d), as γ_g increases, STPB channel gains become large, and SUs reduce their transmission powers to meet the interference constraint. Thus, the secondary network throughput drops as discussed above.

The next theorem establishes the secondary network sum-rate scaling behavior under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$. In Appendix E, we give a detailed proof for this theorem.

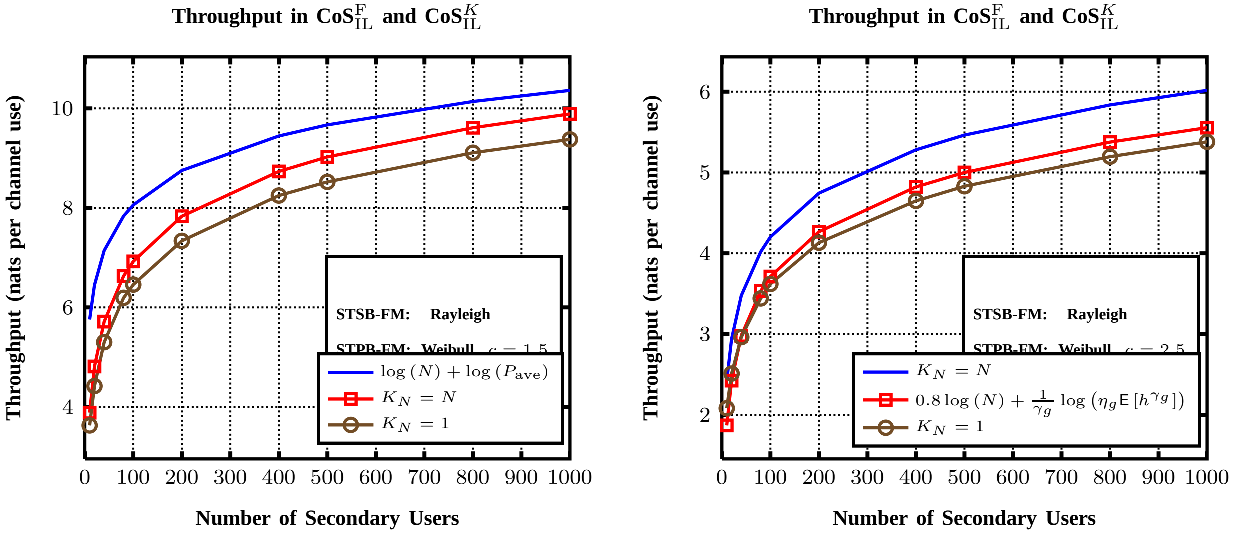
Theorem 4: Let $R_{\mathrm{IPIL}}^{\mathrm{F}}(N)$ and $R_{\mathrm{IPIL}}^{K}(K_N)$ be the secondary network throughput under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$ for $0 < K_N \leq N$, respectively. Then,

$$\lim_{N\to\infty} \frac{R_{\mathrm{IPIL}}^{K}(K_N)}{\log(N)} = \lim_{N\to\infty} \frac{R_{\mathrm{IPIL}}^{\mathrm{F}}(N)}{\log(N)} = \min\left(1, \frac{1}{\gamma_g}\right).$$

Proof: Please see Appendix E. ■

Theorem 4 establishes the logarithmic scaling behavior of the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$ as a function of the number of SUs when the CDFs of STSB and STPB channel gains belong to class $\mathcal{C}$-distributions. For $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$, the scaling behavior does not depend on the number of STPB channel gains available at the SBS. Hence, even for $K_N = O(1)$, a secondary network under $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$ can achieve the same scaling behavior as the one achieved under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$, which implies a tremendous reduction in the primary-secondary feedback load.

Theorem 4 also reveals the effect of parameters of the STPB fading model on the scaling behavior of $R_{\mathrm{IPIL}}^{\mathrm{F}}(N)$ and $R_{\mathrm{IPIL}}^{K}(K_N)$, which appears as the pre-log factor of $\min\left(1, \frac{1}{\gamma_g}\right)$. This effect has the following interpretation. For $\gamma_g < 1$, random STPB channel gains take values close to zero with high probability. As a result, the average interference power constraint becomes increasingly looser, and the transmission powers of SUs become mainly limited by the individual average power constraints, *i.e.*, secondary network behaves as a primary MAC with individual power constraints only. In Lemma 10 in Appendix E, we show that the sum-rate of a primary MAC with individual power constraints $R_{\mathrm{IPL}}(N)$ scales according to $\log N$. Hence, the secondary network throughput scales according to $\log(N)$ for $\gamma_g < 1$. For $\gamma_g > 1$, random STPB channel gains take large values away from zero with high probability, when compared with the case of $\gamma_g < 1$. Thus, the average interference power constraint



(a)

(b)

Fig. 5. Secondary network throughput scaling under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ $(K_N = N)$ and $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$ $(K_N = 1)$ for different communication environments. P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively.

becomes more stringent, and the secondary network behaves as an IL network. This leads to the result that the secondary network throughput scales according to $\frac{1}{\gamma_g}\log(N)$ for $\gamma_g > 1$.

From a more heuristic perspective, the effect of the pre-log factor $\min\left(1, \frac{1}{\gamma_g}\right)$ has the following interpretation. By removing the interference power constraint from an IPIL network, we obtain a primary MAC with individual power constraints whose sum-rate $R_{\mathrm{IPL}}(N)$ can be shown to scale according to $\log(N)$. On the other hand, by removing the individual power constraints from an IPIL network, we obtain an IL network whose throughput $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ can be shown to scale according to $\frac{1}{\gamma_g}\log(N)$. Thus, $R_{\mathrm{IPIL}}^{\mathrm{F}}(N)$ is upper bounded by both $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ and $R_{\mathrm{IPL}}(N)$. Depending on the value of γ_g, one of the upper bounds bites. That is, for $\gamma_g < 1$, $R_{\mathrm{IPL}}(N)$ bound is tighter than $R_{\mathrm{IL}}^{\mathrm{F}}(N)$, and as a result the secondary network throughput scales according to $\log(N)$. For $\gamma_g > 1$, $R_{\mathrm{IL}}^{\mathrm{F}}(N)$ bound is tighter than $R_{\mathrm{IPL}}(N)$, and the secondary network throughput scales according to $\frac{1}{\gamma_g}\log(N)$. It should be noted these arguments can only provide us with an upper bound. More analysis is needed to establish the lower bounds with the same scaling behavior, *i.e.*, see Appendix E.

We demonstrate the sum-rate scaling behavior of the secondary network under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ and $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$ as a function of the number of SUs in Fig. 5. In this figure, the curves with $K_N = N$ represent the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$, and the curves with $K_N = 1$ represent the secondary network sum-rate under $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$. P_{ave} and Q_{ave} are set to 15dB and 0dB, respectively. Similar qualitative behavior continues to hold for other values of P_{ave} and Q_{ave}. Fig. 5(a) illustrates the secondary network throughput scaling when STSB channel gains are distributed according to the Rayleigh fading model, and STPB channel gains are distributed according to the Weibull fading model with $c = 1.5$. Fig. 5(a) indicates that the throughput of the secondary network scales according to $\log(N)$ for $c \leq 2$ as predicted by Theorem 3. The $\log(N) + \log(P_{\mathrm{ave}})$ curve represents the scaling behavior of the primary multiple access channel with individual power constraints obtained by removing the interference power constraint from the original IPIL network. Closeness of this curve to our simulated data rates confirms that an IPIL network behaves similar to a primary MAC with individual power constraints for $\gamma_g < 1$.

Fig. 5(b) represents the secondary network sum-rate when STSB channel gains are distributed according to the Rayleigh fading model, and STPB channel gains are distributed according to the Weibull fading model with $c = 2.5$. As this figure shows, the secondary network throughput scales according to $\frac{2}{c}\log\left(N\right)$ in accordance with the MDGs predicted by Theorem 4. In Fig. 5(b), the $0.8\log\left(N\right) + \frac{1}{\gamma_g}\log\left(\eta_g \mathsf{E}\left[h^{\gamma_g}\right]\right)$ curve quantifies the sum-rate scaling behavior of the IL network obtained by removing the individual power constraints from the original IPIL network. Closeness of this curve to our simulated data rates confirms that an IPIL network behaves similar to an IL network for $\gamma_g > 1$. Finally, Figs. 4(a)-(b) show that the throughput loss arising from implementing the K-SCG feedback protocol is within one nats per channel use again when compared to the full-feedback protocol, which signifies that the K-SCG feedback protocol is an effective primary-secondary feedback reduction policy in this case, too.

IV. CONCLUSION

In this paper, we have analyzed the secondary network sum-rate scaling behavior for cognitive radio multiple access channels in feedback limited communication scenarios. To this end, we have first introduced an efficient primary-secondary feedback protocol called the K-smallest channel gains (K-SCGs) feedback protocol in which the PBS feeds back the K_N smallest STPB channel gains to the SBS (out of N STPB channel gains). The effect of the K-SCG feedback protocol on the secondary network sum-rate scaling behavior has been studied for three different network types when the transmission powers of secondary users (SUs) are optimally allocated. The network types considered are the total-power-and-interference-limited (TPIL), interference-limited (IL) and individual-power-and-interference-limited (IPIL) networks. In TPIL networks, transmit powers of SUs are limited by an average total power constraint as well as a constraint on the average total interference power that they cause to the PBS. On the other hand, transmit powers of SUs are limited by a constraint only on the average total interference power at the PBS for IL networks. In the case of IPIL networks, transmit powers of SUs are limited by individual average power constraints as well as a constraint on the average total interference power at the PBS.

For each network type considered, we have derived a sufficient condition on K_N such that the K-SCG feedback protocol is asymptotically optimal. It has been shown that for $K_N = N^{\delta}$ with $\delta \in (0,1)$, the K-SCG feedback protocol is asymptotically optimal in TPIL networks, *i.e.*, the secondary network sum-rate under K-SCG and full-feedback protocols scales according to $\frac{1}{n_h}\log\log\left(N\right)$, where n_h is a parameter obtained from the distribution of the STSB channel power gains and N is the number of SUs. In TPIL networks, it has also been shown that for K_N growing to infinity at a rate $K_N = o\left(N\right)$, the interference power at the PBS converges to zero almost surely and in mean as N becomes large. Once this happens, the secondary network just requires the indices of SUs having the K_N smallest STSB channel gains for the jointly optimal power allocation and scheduling as N becomes large. For IL networks, It has been shown that having $K_N = O\left(1\right)$ is enough for the asymptotical optimality of the K-

SCG feedback protocol. In this case, the secondary network sum-rate under K-SCG and full-feedback protocols scales according to $\frac{1}{\gamma_g}\log\left(N\right)$, where γ_g is a parameter controlling the decay rate of the CDF of the STPB channel gains around zero. $K_N = O\left(1\right)$ is also enough for the asymptotical optimality of the K-SCG for IPIL networks. In this case, the secondary network sum-rate under K-SCG and full-feedback protocols scales according to $\min\left(1, \frac{1}{\gamma_g}\right)\log\left(N\right)$.

APPENDIX A

ASYMPTOTIC BEHAVIOR OF EXTREME ORDER STATISTICS

In this appendix, we study the concentration behavior of the extreme order statistic of a sequence of i.i.d. random variables as the number of elements in the sequence grows large. Later, this result will play a central role in deriving the cognitive radio throughput scaling behavior in different communication scenarios. To this end, let $\left\{Y_i\right\}_{i=1}^{N}$ be a sequence of i.i.d random variables with a common probability distribution function $F(x)$. We assume that $\lim_{x\to\infty} F(x) = 1$, $F(x) < 1$ for $x < \infty$, and there exists $x_0 < \infty$ such that $F\left(x_1\right) < F\left(x_2\right)$ whenever $x_0 < x_1 < x_2 < \infty$. We call a CDF possessing these properties an *eventually increasing* CDF. Let $G(x)$ be a function such that $\lim_{x\to\infty} G(x)\left(1 - F(x)\right) = 1$. We say $G(x)$ characterizes the tail behavior of $F(x)$. Without loss of generality, we assume that $G(x) : (C, \infty) \mapsto \mathbb{R}_+$, and $G(x)$ is strictly increasing on (C, ∞). Note that $G(x)$ is invertible, and we denote its functional inverse as $G^{-1}(x)$.[1] Let $Y_N^\star$ be the extreme order statistic of $\left\{Y_i\right\}_{i=1}^{N}$, *i.e.*, $Y_N^\star = \max\limits_{1\leq i\leq N} Y_i$. Let $F_N^\star(x)$ be the CDF of $Y_N^\star$.

The next lemma establishes an important concentration property for $Y_N^\star$. This result will be used to study the convergence behavior of $Y_N^\star$. It also shows that the asymptotic behavior of $Y_N^\star$ is characterized by $G(x)$ as N tends to infinity. Note that the class of eventually increasing distributions covers the class $\mathcal{C}$ distributions.

Lemma 2: Let $\left\{Y_i\right\}_{i=1}^{N}$ be a sequence of i.i.d. random variables with an eventually increasing common CDF $F(x)$ whose tail behavior is characterized by $G(x)$. Also, let $Y_N^\star = \max_{1\leq i\leq N} Y_i$. Then, for any ϵ belonging to $(0, 1)$, we have

$$\lim_{N\to\infty} \mathsf{Pr}\left\{G^{-1}\left(N^{1-\epsilon}\right) < Y_N^\star \leq G^{-1}\left(N^{1+\epsilon}\right)\right\} = 1. \tag{18}$$

Proof: For x large enough, we can express $F_N^\star(x)$ as $F_N^\star(x) = \mathrm{e}^{-N\Theta\left(\frac{-1}{G(x)}\right)}$ since $\lim_{x\to\infty} G(x)\left(1 - F(x)\right) = 1$. By using this expression for $F_N^\star(x)$, we have:

$$\begin{aligned} \mathsf{Pr}\left\{Y_N^\star \leq G^{-1}\left(N^{1+\epsilon}\right)\right\} &= \mathrm{e}^{-N\Theta\left(\frac{1}{N^{1+\epsilon}}\right)} \\ &= 1 - \Theta\left(\frac{1}{N^\epsilon}\right), \end{aligned} \tag{19}$$

---

[1] Since $F(x)$ is eventually increasing, $G(x)$ is also eventually increasing and tends to infinity as x tends to infinity. Thus, we can find a large positive constant C such that $G(x)$ is strictly increasing on (C, ∞), and $G(x)$ is invertible on this interval.

and

$$\begin{aligned}\mathsf{Pr}\left\{Y_N^\star \le G^{-1}\left(N^{1-\epsilon}\right)\right\} &= \mathrm{e}^{-N\Theta\left(\frac{1}{N^{1-\epsilon}}\right)} \\ &= \mathrm{e}^{-\Theta(N^\epsilon)}. \qquad (20)\end{aligned}$$

for all $\epsilon \in (0,1)$ and N large enough. Therefore, we have

$$\mathsf{Pr}\left\{G^{-1}\left(N^{1-\epsilon}\right) < Y_N^\star \le G^{-1}\left(N^{1+\epsilon}\right)\right\} = 1 - \Theta\left(\frac{1}{N^\epsilon}\right), \qquad (21)$$

which implies that $Y_N^\star$ lies in $\left[G^{-1}\left(N^{1-\epsilon}\right), G^{-1}\left(N^{1+\epsilon}\right)\right]$ with probability approaching 1 as N grows large. ■

APPENDIX B

THROUGHPUT SCALING IN TOTAL-POWER-AND-INTERFERENCE-LIMITED SCENARIO

The asymptotic behavior of $R_{\text{TPIL}}^{\text{F}}(N)$ and $R_{\text{TPIL}}^{K}(K_N)$ depends on the asymptotic behavior of $X_N^\star(\lambda_N, \mu_N) = \max\limits_{1\le i\le N} \frac{h_i}{\lambda_N + \mu_N g_i}$ and $X_{K_N}^\star(\lambda_N, \mu_N) = \max_{1\le i\le K_N} \frac{h_{\pi(i)}}{\lambda_N + \mu_N g_{\pi(i)}}$ as a function of N, respectively. Since Lagrange multipliers λ_N and μ_N, which can be different for different communication scenarios, vary with N, $\left\{\frac{h_i}{\lambda_N + \mu_N g_i}\right\}_{i=1}^{N}$ and $\left\{\frac{h_{\pi(i)}}{\lambda_N + \mu_N g_{\pi(i)}}\right\}_{i=1}^{K_N}$ form triangular arrays of random variables. This complicates the analysis to some extent. Hence, to simplify our analysis, we start with the characterization of the asymptotic behavior of $X_N^\star(\lambda, \mu)$ and $X_{K_N}^\star(\lambda, \mu)$ for some fixed non-negative real numbers λ and μ. Then, we use this result to obtain the asymptotic behavior of $R_{\text{TPIL}}^{\text{F}}(N)$ and $R_{\text{TPIL}}^{K}(K_N)$ for large values of N.

The next three assisting lemmas play a key role in the proof Theorem 1. Recall that all distribution functions belong to the class $\mathcal{C}$ distributions, and therefore, the various parameters such as $\alpha, l, \beta, n, H(x), \gamma$ and η appearing in our analysis below are as defined in Definition 2.1. For specific channel models, they are given in Table II.

Let $\tilde{R}(N, \lambda, \mu) = \mathsf{E}\left[\log\left(X_N^\star(\lambda, \mu)\right) 1_{\{X_N^\star(\lambda,\mu)\ge 1\}}\right]$. In the next lemma, we establish the asymptotic behavior of $\tilde{R}(N, \lambda, 0)$, which will be helpful in upper bounding the sum-rate in $\text{CoS}_{\text{TPIL}}^{\text{F}}$.

Lemma 3: For $\lambda > 0$, $\lim_{N\to\infty} \frac{\tilde{R}(N,\lambda,0)}{\log\left(\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log(\alpha_h N)\right)^{\frac{1}{n_h}}\right)} = 1$.

Proof: Let $\tilde{X}_N^\star(\lambda, 0) = \frac{\log(X_N^\star(\lambda,0))}{\log\left(\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log(\alpha_h N)\right)^{\frac{1}{n_h}}\right)} 1_{\{X_N^\star(\lambda,0)\ge 1\}}$. Hence, to show the desired result, it is enough to show $\lim_{N\to\infty} \mathsf{E}\left[\tilde{X}_N^\star(\lambda, 0)\right] = 1$. Note that $X_N^\star(\lambda, 0) = \frac{1}{\lambda} h_N^\star$, where $h_N^\star = \max_{1\le i\le N} h_i$. Recall $F_h(x)$ is the probability distribution function common to all h_i, $1 \le i \le N$. From (1), the tail behavior of $F_h(x)$ is characterized as $G(x) = \frac{x^{-l_h}}{\alpha_h} \mathrm{e}^{\beta_h x^{n_h} - H(x)}$. Hence, we can write $G^{-1}(x) = \left(\frac{\frac{1}{\beta_h}\log(\alpha_h x)}{1 - \frac{l_h \log\left(G^{-1}(x)\right) + H\left(G^{-1}(x)\right)}{\beta\left(G^{-1}(x)\right)^{n_h}}}\right)^{\frac{1}{n_h}}$. Note that $1 - \frac{l_h \log(G^{-1}(x)) + H(G^{-1}(x))}{\beta_h (G^{-1}(x))^{n_h}} = 1 - o(1)$. Thus, $G^{-1}(x) = \left(\frac{1}{\beta_h}\log(\alpha_h x)\right)^{\frac{1}{n_h}}(1 + o(1))$. Using Lemma 2, we have

$$\begin{aligned}
&\mathsf{Pr}\left\{G^{-1}\left(\alpha_h^{-\epsilon}N^{1-\epsilon}\right) < h_N^\star \le G^{-1}\left(\alpha_h^{\epsilon}N^{1+\epsilon}\right)\right\}\\
&\qquad = \mathsf{Pr}\left\{\left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)^{\frac{1}{n_h}}\left(1-\epsilon\right)^{\frac{1}{n}}\left(1+o\left(1\right)\right) < h_N^\star \le \left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)^{\frac{1}{n_h}}\left(1+\epsilon\right)^{\frac{1}{n}}\left(1+o\left(1\right)\right)\right\}\\
&\qquad = 1-\Theta\left(\frac{1}{N^\epsilon}\right) \qquad (22)
\end{aligned}$$

for N large enough. This final result implies that $\tilde{X}_N^\star\left(\lambda,0\right) \xrightarrow{i.p.} 1$ as N goes to infinity, where $i.p.$ stands for in probability.

Since convergence in probability does not alway imply convergence in mean, we need to prove that $\left\{\tilde{X}_N^\star\left(\lambda,0\right)\right\}_{N=1}^\infty$ is a uniformly integrable collection of random variables, or equivalently $\lim_{C\to\infty}\sup_{N\ge1}\mathsf{E}\left[\tilde{X}_N^\star\left(\lambda,0\right)\mathsf{1}_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right] = 0$, to conclude the proof [25]. To prove uniform integrability of $\left\{\tilde{X}_N^\star\left(\lambda,0\right)\right\}_{N=1}^\infty$, it is enough to prove that the collection of random variables $\left\{\tilde{X}_N^\star\left(\lambda,0\right)\right\}_{N\ge N_0}$ is uniformly integrable for some finite positive integer N_0 [26]. To this end, we will show that for any given ϵ_1, ϵ_2 and ϵ_3 satisfying $\epsilon_1>0$, $0<\epsilon_2<\beta_h$ and $\epsilon_3>0$, we can find large enough positive constants N_0 and C_0 such that

$$\sup_{N\ge N_0}\mathsf{E}\left[\tilde{X}_N^\star\left(\lambda,0\right)\mathsf{1}_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right] \le \left(1+\epsilon_1\right)\left(1+\epsilon_3\right)\alpha N_0\lambda^l\frac{CB_{N_0}^{lC}}{\mathrm{e}^{(\beta-\epsilon_2)\lambda^n B_{N0}^{nC}}}\sum_{i=0}^{\infty}\frac{\left(i+2\right)B_{N_0}^{iCl}}{\mathrm{e}^{B_{N0}^{niC}}} \tag{23}$$

for all C greater than C_0, where $B_N=\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)^{\frac{1}{n_h}}$. Observe that $\sum_{i=0}^\infty\frac{(i+2)B_{N_0}^{iCl}}{\mathrm{e}^{B_{N0}^{niC}}}$ is a convergent series for N_0 large enough. Thus, $\lim_{C\to\infty}\sup_{N\ge N_0}\mathsf{E}\left[\tilde{X}_N^\star\left(\lambda,0\right)\mathsf{1}_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right]=0$, which implies $\left\{\tilde{X}_N^\star\left(\lambda,0\right)\right\}_{N=1}^\infty$ is uniformly integrable. The rest of the proof is devoted to show that (23) holds.

For $C>0$, $\mathsf{E}\left[\tilde{X}_N^\star\left(\lambda,0\right)\mathsf{1}_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right]$ can be upper bounded as

$$\begin{aligned}
\mathsf{E}\left[\tilde{X}_N^\star\left(\lambda,0\right)\mathsf{1}_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right] &\le \sum_{i=1}^{\infty}\left(i+1\right)C\,\mathsf{Pr}\left\{iC<\tilde{X}_N^\star\left(\lambda,0\right)\le\left(i+1\right)C\right\}\\
&\le \sum_{i=1}^{\infty}\left(i+1\right)C\,\mathsf{Pr}\left\{\lambda B_N^{iC}<h_N^\star\right\}. \qquad (24)
\end{aligned}$$

For any given $\epsilon_1>0$, $<\epsilon_2<\beta_h$, $\epsilon_3>0$ and N large enough, $\mathsf{Pr}\left\{\lambda B_N^{iC}<h_N^\star\right\}$ can be upper bounded as

$$\begin{aligned}
\mathsf{Pr}\left\{\lambda B_N^{iC}<h_N^\star\right\} &= 1-F_h^N\left(\lambda B_N^{iC}\right)\\
&\overset{\text{(a)}}{\le} 1-\mathrm{e}^{N\log\left(1-\frac{(1+\epsilon_1)\alpha_h\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{\beta_h\left(\lambda B_N^{iC}\right)^{n_h}-H\left(\lambda B_N^{iC}\right)}}\right)}\\
&\overset{\text{(b)}}{\le} 1-\mathrm{e}^{N\log\left(1-\frac{(1+\epsilon_1)\alpha_h\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{\left(\beta_h-\epsilon_2\right)\left(\lambda B_N^{iC}\right)^{n_h}}}\right)}\\
&\overset{\text{(c)}}{\le} 1-\mathrm{e}^{-(1+\epsilon_1)(1+\epsilon_3)\frac{\alpha_h N\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{\left(\beta_h-\epsilon_2\right)\left(\lambda B_N^{iC}\right)^{n_h}}}}\\
&\overset{\text{(d)}}{\le} \left(1+\epsilon_1\right)\left(1+\epsilon_3\right)\frac{\alpha_h N\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}},
\end{aligned}$$

where (a) follows from the fact that for all $\epsilon_1>0$ and x large enough, $F_h(x)$ can be lower bounded as $F_h(x)\ge$

$1-\frac{(1+\epsilon_1)\alpha x^{l_h}}{\mathrm{e}^{\beta_h x^{n_h}-H(x)}}$ by Definition 2.1, (b) follows from the fact that for all $\epsilon_2 \in (0,\beta)$ and x large enough, $H(x)$ can be upper bounded as $H(x) < \epsilon_2 x^{n_h}$ since $H(x) = o(x^{n_h})$, (c) follows from the fact that for all $\epsilon_3 > 0$ and $x > 0$ close enough to zero, $\log(1-x)$ can be lower bounded as $\log(1-x) \geq -(1+\epsilon_3)x$ since $\lim_{x\downarrow 0}\frac{\log(1-x)}{x} = -1$, and finally (d) follows form the fact that $\mathrm{e}^{-x} \geq 1-x$ for $x \geq 0$. Thus, for all $\epsilon_1 > 0$, $< \epsilon_2 < \beta_h$, $\epsilon_3 > 0$ and N large enough, $\mathsf{E}\left[\tilde{X}_N^\star(\lambda,0)\,1_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right]$ can be upper bounded as

$$\mathsf{E}\left[\tilde{X}_N^\star(\lambda,0)\,1_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right] \;\leq\; \sum_{i=1}^{\infty}(i+1)\,C\,(1+\epsilon_1)(1+\epsilon_3)\,\frac{\alpha_h N\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}.$$

Now, we show that there exist large enough positive constants N_0 and C_0 such that $\frac{N(\lambda B_N^{iC})^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}$ is a decreasing function of N for $N \geq N_0$ whenever C is fixed but larger than C_0. By considering N as a positive real number with a slight abuse of notation, the first derivative of $\frac{N(\lambda B_N^{iC})^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}$ with respect to N can be obtained as

$$\frac{\partial}{\partial N}\frac{N\left(\lambda B_N^{iC}\right)^{l_n}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}} \;=\; \frac{iCB_N^{(iC-1)n_h}\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}\left(\frac{1}{iCB_N^{(iC-1)n_h}}+\frac{l}{n_h\lambda^{n_h}\beta_h B_N^{iCn_h}}-\frac{(\beta_h-\epsilon_2)}{\beta_h}\right).$$

This final equation implies that we can find large enough positive constants C_0 and N_0 such that $B_{N_0} > 1$ and $\frac{1}{CB_N^{(iC-1)n_h}}+\frac{l}{n_h\lambda^{n_h}\beta B_N^{iCn_h}}-\frac{(\beta_h-\epsilon_2)}{\beta_h} < 0$ for $C \geq C_0$, $N \geq N_0$ and $i \in \mathbb{N}$. Finally, we have

$$\begin{aligned}
\sup_{N\geq N_0}\mathsf{E}\left[\tilde{X}_N^\star(\lambda,0)\,1_{\left\{\tilde{X}_N^\star(\lambda,0)>C\right\}}\right] \;&\leq\; \sup_{N\geq N_0}\sum_{i=1}^{\infty}(i+1)\,C\,(1+\epsilon_1)(1+\epsilon_3)\,\frac{\alpha_h N\left(\lambda B_N^{iC}\right)^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}\\
&\overset{\text{(a)}}{=}\; \sum_{i=1}^{\infty}(i+1)\,C\,(1+\epsilon_1)(1+\epsilon_3)\,\frac{\alpha_h N_0\left(\lambda B_{N_0}^{iC}\right)^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_{N0}^{iC})^{n_h}}}\\
&=\; C(1+\epsilon_1)(1+\epsilon_3)\,\alpha_h N_0\lambda^{l_h}B_{N_0}^{Cl_h}\sum_{i=0}^{\infty}\frac{(i+2)\,B_{N_0}^{iCl_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)\lambda^{n_h}B_{N0}^{iCn_h}B_{N0}^{Cn_h}}}\\
&\overset{\text{(b)}}{\leq}\; (1+\epsilon_1)(1+\epsilon_3)\,\alpha_h N_0\lambda^{l_h}\frac{CB_{N_0}^{Cl_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)\lambda^{n_h}B_{N0}^{Cn_h}}}\sum_{i=0}^{\infty}\frac{(i+2)\,B_{N_0}^{iCl_h}}{\mathrm{e}^{B_{N0}^{iCn_h}}},
\end{aligned} \tag{25}$$

where (a) follows from the fact that $\frac{N(\lambda B_N^{iC})^{l_h}}{\mathrm{e}^{(\beta_h-\epsilon_2)(\lambda B_N^{iC})^{n_h}}}$ is decreasing with N for $N \geq N_0$ and $C \geq C_0$, and (b) follows from the fact that $B_{N0}^{iCn_h}B_{N0}^{Cn_h} \geq B_{N0}^{Cn_h}+B_{N0}^{iCn_h}$ for N_0 large enough, which completes the proof. ■

The next lemma will assist us to upper and lower lower bound the sum-rate in $\mathrm{CoS}_{\mathrm{TPIL}}^{K}$.

Lemma 4: For $\lambda > 0$, $\mu > 0$ and K_N growing to infinity at a rate $K_N = o(N)$, we have

$$\lim_{N\to\infty}\frac{\tilde{R}(K_N,\lambda,\mu)}{\log\left(\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log(\alpha_h K_N)\right)^{\frac{1}{n_h}}\right)} = 1.$$

Proof: Let $\tilde{X}_{K_N}^\star(\lambda,\mu) = \frac{\log\left(X_{K_N}^\star(\lambda_h,\mu)\right)}{\log\left(\frac{1}{\lambda_h}\left(\frac{1}{\beta_h}\log(\alpha_h K_N)\right)^{\frac{1}{n_h}}\right)}1_{\left\{X_{K_N}^\star(\lambda,\mu)\geq 1\right\}}$. First, we show that $\tilde{X}_{K_N}^\star(\lambda,\mu) \xrightarrow{i.p.} 1$ as N grows large. To this end, we will show that $g_{\pi(K_N)}$ converges to zero in probability. The CDF of the K_Nth smallest value for the collection of random variables $\{g_i\}_{i=1}^{N}$, which we denote as $F_g^{(K_N)}(x)$, is given by

$$F_g^{(K_N)}(x) \;=\; \int_0^{F_g(x)} \frac{x^{K_N-1}(1-x)^{N-K_N}}{\mathsf{B}\left(K_N, N-K_N+1\right)}dx, \tag{26}$$

where $\mathsf{B}(a,b)=\int_0^1 t^{a-1}(1-t)^{b-1}dt$ is the beta function [22], and $F_g(x)$ is the CDF common to all g_i, $1 \leq i \leq N$. We define z_{K_N} as $z_{K_N} = F_g\left(g_{\pi(K_N)}\right)$. Using (26), the CDF of z_{K_N}, which we denote as $F_{z_{K_N}}(x)$, is given as

$$\begin{aligned} F_{z_{K_N}}(x) &= \mathsf{Pr}\left\{z_{K_N} \leq x\right\} \\ &\overset{\text{(a)}}{=} \mathsf{Pr}\left\{g_{K_N:N} \leq F_g^{-1}(x)\right\} \\ &= \int_0^{x} \frac{x^{K_N-1}(1-x)^{N-K_N}}{\mathsf{B}\left(K_N, N-K_N+1\right)}dx, \end{aligned} \tag{27}$$

where (a) follows from the fact that $F_g(x)$ is invertible and monotone increasing for $x>0$ and $g_{\pi(K_N)} = g_{K_N:N}$. Note that the random variable X is said to be Beta distributed with parameters v and w if its CDF is given by $F_X\left(x\right) = \int_0^x \frac{t^{v-1}(1-t)^{w-1}}{\mathsf{B}(v,w)}dt$. Thus, z_{K_N} is indeed a Beta distributed random variable with parameters K_N and $N-K_N+1$. Using the fact that z_{K_N} is Beta distributed, we can upper bound the tail probability $\mathsf{Pr}\left\{g_{\pi(K_N)} > \epsilon\right\}$ of $g_{\pi(K_N)}$ for all $\epsilon > 0$ as

$$\begin{aligned} \mathsf{Pr}\left\{g_{\pi(K_N)} > \epsilon\right\} &= \mathsf{Pr}\left\{F_g\left(g_{\pi(K_N)}\right) > F\left(\epsilon\right)\right\} \\ &= \mathsf{Pr}\left\{z_{K_N} > F\left(\epsilon\right)\right\} \\ &\overset{\text{(a)}}{\leq} \frac{\mathsf{E}\left[z_{K_N}\right]}{F\left(\epsilon\right)} \\ &\overset{\text{(b)}}{=} \frac{K_N}{F\left(\epsilon\right)\left(N+1\right)}, \end{aligned} \tag{28}$$

where (a) follows from the Markov inequality, and (b) follows from the formula $\mathsf{E}\left[z_{K_N}\right] = \frac{K_N}{N+1}$ for the mean value of Beta distributed random variables [24]. This implies $g_{\pi(K_N)} \xrightarrow{i.p.} 0$ as N grows large. We will use this convergence property of $g_{\pi(K_N)}$ while we obtain a tight lower bound for $X_{K_N}^{\star}\left(\lambda,\mu\right)$, hence for $\tilde{X}_{K_N}^{\star}\left(\lambda,\mu\right)$, below.

We note that the collection of random variables $\left\{h_{\pi(i)}\right\}_{i=1}^{K_N}$ are i.i.d. with the common distribution $F_h\left(x\right)$ because $\boldsymbol{h}$ and $\boldsymbol{g}$ are independent, and our selection criterion depends on $\boldsymbol{g}$. Since $g_{\pi(K_N)}$ is the largest value in $\left\{g_{\pi(i)}\right\}_{i=1}^{K_N}$, $X_{K_N}^{\star}\left(\lambda,\mu\right)$ can be lower bounded as $\max\limits_{1\leq i \leq K_N} \frac{h_{\pi(i)}}{\lambda+\mu g_{\pi(K_N)}} \leq X_{K_N}^{\star}\left(\lambda,\mu\right)$. Therefore, we obtain the following upper and lower bounds for $X_{K_N}^{\star}\left(\lambda,\mu\right)$:

$$\frac{h_{K_N}^{\star}}{\lambda+\mu g_{\pi(K_N)}} \leq X_{K_N}^{\star}\left(\lambda,\mu\right) \leq \frac{h_{K_N}^{\star}}{\lambda}, \tag{29}$$

where $h_{K_N}^{\star} = \max_{1\leq i\leq K_N} h_{\pi(i)}$. From continuous mapping theorem [25], we have $\frac{1}{1+\frac{\mu}{\lambda}g_{\pi(K_N)}} \xrightarrow{i.p.} 1$ as N grows large, which implies $\frac{\frac{1}{1+\frac{\mu}{\lambda}g_{\pi(K_N)}}\frac{h_{K_N}^{\star}}{\lambda}}{\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log(\alpha_h K_N)\right)^{\frac{1}{n_h}}} \xrightarrow{i.p.} 1$ as N grows large by using Lemma 3. Thus, $\frac{X_{K_N}^{\star}(\lambda,\mu)}{\frac{1}{\lambda}\left(\frac{1}{\beta_h}\log(\alpha_h K_N)\right)^{\frac{1}{n_h}}}$ converges to 1 in probability, which, in turn, implies the convergence of $\tilde{X}_{K_N}^{\star}\left(\lambda,\mu\right)$ to 1 in probability. The proof of uniform integrability is similar to that in Lemma 3. ■

In the next lemma, we establish an important convergence property for the Lagrange multiplier λ_N as N grows large. This result will be used to obtain lower and upper bounds for the sum-rate in $\text{CoS}^K_{\text{TPIL}}$ and to show the logarithmic effect of P_{ave} on the secondary network throughput under $\text{CoS}^K_{\text{TPIL}}$.

Lemma 5: Let λ_N be the Lagrange multiplier corresponding to the average total transmit power constraint in $\text{CoS}^K_{\text{TPIL}}$. Then, $\lim_{N\to\infty} \lambda_N = \frac{1}{P_{\text{ave}}}$.

Proof: First, we show that $\liminf_{N\to\infty} \lambda_N > 0$ by contradiction. Assume that $\liminf_{N\to\infty} \lambda_N = 0$. This means that, for any given $\epsilon > 0$, we can find a subsequence $\{N_j\}_{j=1}^{\infty}$ such that $\lambda_{N_j} \leq \epsilon$ for N_j large enough. Recall $P^\star_{i^\star_{K_N}, K_N}(\boldsymbol{h}, \boldsymbol{g}) = \left(\frac{1}{\lambda_N + \mu_N g_{i^\star_{K_N}}} - \frac{1}{h_{i^\star_{K_N}}}\right)^+$, where $i^\star_{K_N} = \pi\left(\arg \max_{1\leq i\leq K_N} \frac{h_{\pi(i)}}{\lambda_N + \mu_N g_{\pi(i)}}\right)$. The average total transmit power of the secondary network for N_j large enough can be lower bounded as

$$\begin{aligned}
\mathsf{E}\left[P^\star_{i^\star_{K_{N_j}}, K_{N_j}}(\boldsymbol{h}, \boldsymbol{g})\right] &\overset{(a)}{\geq} \mathsf{E}\left[\left(\frac{\frac{h^\star_{K_{N_j}}}{\lambda_{N_j} + \mu_{N_j} g_{\pi(K_{N_j})}} - 1}{h^\star_{K_{N_j}}}\right)^+\right] \\
&= \mathsf{E}\left[\left(\frac{1}{\lambda_{N_j} + \mu_{N_j} g_{\pi(K_{N_j})}} - \frac{1}{h^\star_{K_{N_j}}}\right)^+\right] \\
&\geq \mathsf{E}\left[\left(\frac{1}{\epsilon + \mu_{N_j} g_{\pi(K_{N_j})}} - \frac{1}{h^\star_{K_{N_j}}}\right)^+\right], \qquad (30)
\end{aligned}$$

where $h^\star_{K_{N_j}} = \max_{1\leq i\leq K_{N_j}} h_{\pi(i)}$ and (a) follows from the inequality that $g_{\pi(i)} \leq g_{\pi(K_{N_j})}$ for all $i \in \left\{1, \ldots, K_{N_j}\right\}$. Note that the Lagrange multiplier for the average interference power can be upper bounded as $\mu_N \leq \frac{1}{Q_{\text{ave}}}$ for all N, and also $\frac{1}{h^\star_{K_{N_j}}} \xrightarrow{i.p} 0$ as N_j grows large. Therefore, $\left(\frac{1}{\epsilon + \mu_{N_j} g_{\pi(K_{N_j})}} - \frac{1}{h^\star_{K_{N_j}}}\right)^+ \xrightarrow{i.p} \frac{1}{\epsilon}$ as N_j goes to infinity. Applying Fatou's Lemma to, we have

$$\begin{aligned}
\liminf_{N_j\to\infty} \mathsf{E}\left[\left(\frac{1}{\lambda_{N_j} + \mu_{N_j} g_{i^\star_{K_{N_j}}}} - \frac{1}{h_{i^\star_{K_{N_j}}}}\right)^+\right] &\geq \liminf_{N_j\to\infty} \mathsf{E}\left[\left(\frac{1}{\epsilon + \mu_{N_j} g_{\pi(K_{N_j})}} - \frac{1}{h^\star_{K_{N_j}}}\right)^+\right] \\
&\geq \frac{1}{\epsilon}.
\end{aligned}$$

This implies that the average total transmit power constraint will be violated when N_j is large enough if we choose ϵ sufficiently small. Thus, we conclude that $\liminf_{N\to\infty} \lambda_N > 0$.

Now, we will conclude the proof by using the fact that λ_N cannot be arbitrarily close to zero. The average total transmit power constraint can be written as $P_{\text{ave}} = \mathsf{E}\left[\left(\frac{1}{\lambda_N + \mu_N g_{i^\star_{K_N}}} - \frac{1}{h_{i^\star_{K_N}}}\right)^+\right]$. This implies $\lambda_N \leq \frac{1}{P_{\text{ave}}}$ for all N, and hence $\limsup_{N\to\infty} \lambda_N \leq \frac{1}{P_{\text{ave}}}$. Following similar steps that we used to drive (30), λ_N can be lower bounded as $\lambda_N \geq \frac{1}{P_{\text{ave}}} \mathsf{E}\left[\left(\frac{1}{1 + \frac{\mu_N}{\lambda_N} g_{\pi(K_N)}} - \frac{\lambda_N}{h^\star_{K_N}}\right)^+\right]$. Since $\liminf_{N\to\infty} \lambda_N > 0$ and $\mu_N \leq \frac{1}{Q_{\text{ave}}}$, we have $\frac{1}{1 + \frac{\mu_N}{\lambda_N} g_{\pi(K_N)}} \xrightarrow{i.p.} 1$ as N goes to infinity (*i.e.*, see the proof of Lemma 4 for the convergence of $g_{\pi(K_N)}$ to 0 in probability). We also have $\frac{\lambda_N}{h^\star_{K_N}} \xrightarrow{i.p.} 0$ as N goes to infinity because $\lambda_N \leq \frac{1}{P_{\text{ave}}}$. Thus, $\left(\frac{1}{1 + \frac{\mu_N}{\lambda_N} g_{\pi(K_N)}} - \frac{\lambda_N}{h^\star_{K_N}}\right)^+$

converges to 1 in probability. Applying Fatou's Lemma, we have

$$\begin{aligned}\liminf_{N\to\infty}\lambda_N &\geq \frac{1}{P_{\text{ave}}}\liminf_{N\to\infty}\mathsf{E}\left[\left(\frac{1}{1+\frac{\mu_N}{\lambda_N}g_{\pi(K_N)}}-\frac{1}{h^\star_{K_N}}\right)^+\right]\\ &\geq \frac{1}{P_{\text{ave}}},\end{aligned} \tag{31}$$

which completes the proof. ■

A. *Proof of Throughput Scaling in CoS$_{\text{TPIL}}^{K}$*

We first note that $\tilde{R}\left(K_N,\lambda,\mu\right)$ is a decreasing function of λ and μ. Thus, for any given $\epsilon>0$, we can find a constant N_0 large enough such that $R_{\text{TPIL}}^{K}\left(K_N\right)$ can be upper and lower bounded as

$$\tilde{R}\left(K_N,\frac{1+\epsilon}{P_{\text{ave}}},\frac{1}{Q_{\text{ave}}}\right)\leq R_{\text{TPIL}}^{K}\left(K_N\right)\leq\tilde{R}\left(K_N,\frac{1-\epsilon}{P_{\text{ave}}},0\right) \tag{32}$$

for all $N\geq N_0$ since λ_N converges to $\frac{1}{P_{\text{ave}}}$ by Lemma 5 and $\mu_N\leq\frac{1}{Q_{\text{ave}}}$. Using Lemma 4, for any given $\epsilon>0$ and N large enough, $R_{\text{TPIL}}^{K}\left(K_N\right)$ can be further upper and lower bounded as

$$\begin{aligned}&(1-\epsilon)\left[\log\left(\frac{P_{\text{ave}}}{1+\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h K_N\right)\right)\right]\\ &\qquad\leq R_{\text{TPIL}}^{K}\left(K_N\right)\leq(1+\epsilon)\left[\log\left(\frac{P_{\text{ave}}}{1-\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h K_N\right)\right)\right],\end{aligned} \tag{33}$$

which implies

$$\lim_{N\to\infty}\frac{R_{\text{TPIL}}^{K}\left(K_N\right)}{\log\left(\log\left(K_N\right)\right)}=\frac{1}{n_h}.$$

B. *Proof of Throughput Scaling in CoS$_{\text{TPIL}}^{\text{F}}$*

Consider a secondary network under CoS$_{\text{TPIL}}^{\text{F}}$ with a total average transmit power constraint P_{ave}, total average interference power constraint Q_{ave} and N SUs. By removing the average interference power constraint, we obtain a primary MAC network with a total average transmit power constraint P_{ave}. Hence, the sum-rate in CoS$_{\text{TPIL}}^{\text{F}}$ can be upper bounded by the sum-rate $R_{\text{TPL}}\left(N\right)$ of the primary MAC network with the same total average transmit power constraint, *i.e.*, $R_{\text{TPIL}}^{\text{F}}\left(N\right)\leq R_{\text{TPL}}\left(N\right)$. In the next lemma, we establish the asymptotic scaling behavior of $R_{\text{TPL}}\left(N\right)$, which will also serve as an upper bound for $R_{\text{TPIL}}^{\text{F}}\left(N\right)$.

Lemma 6: $R_{\text{TPL}}\left(N\right)$ scales according to $\lim_{N\to\infty}\frac{R_{\text{TPL}}(N)}{\log\log(N)}=\frac{1}{n_h}$. Furthermore, for any given $\epsilon>0$, there exists a constant N_0 large enough such that

$$(1-\epsilon)\left[\log\left(\frac{P_{\text{ave}}}{1+\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)\right]\leq R_{\text{TPL}}\left(N\right)\leq(1+\epsilon)\left[\log\left(\frac{P_{\text{ave}}}{1-\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)\right]$$

for all $N\geq N_0$.

Proof: Since the proof is similar to the analysis given above, we skip it to avoid repetitions. ■

The proof of throughput scaling in $\mathrm{CoS}^{\mathrm{F}}_{\mathrm{TPIL}}$ is completed if we obtain a lower bound for $R^{\mathrm{F}}_{\mathrm{TPIL}}\left(N\right)$ that also scales according to $\frac{1}{n_h}\log\log\left(N\right)$ as N grows large. To this end, we observe that $R^{K}_{\mathrm{TPIL}}\left(K_N\right)$ serves as a lower bound for $R^{\mathrm{F}}_{\mathrm{TPIL}}\left(N\right)$ since more information is available at the SBS to perform power control and user scheduling under $\mathrm{CoS}^{\mathrm{F}}_{\mathrm{TPIL}}$. Thus, for any given $\epsilon > 0$, $0 < \delta < 1$ and N large enough, we have

$$\begin{aligned}(1-\epsilon)\left[\log\left(\frac{P_{\mathrm{ave}}}{1+\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h N^{\delta}\right)\right)\right]&\\ \leq R^{\mathrm{F}}_{\mathrm{TPIL}}\left(N\right) \leq (1+\epsilon)\left[\log\left(\frac{P_{\mathrm{ave}}}{1-\epsilon}\right)+\frac{1}{n_h}\log\left(\frac{1}{\beta_h}\log\left(\alpha_h N\right)\right)\right]&, \quad (34)\end{aligned}$$

which implies

$$\lim_{N\to\infty}\frac{R^{\mathrm{F}}_{\mathrm{TPIL}}\left(N\right)}{\log\left(\log\left(N\right)\right)} = \frac{1}{n_h}. \quad (35)$$

APPENDIX C

SCALING BEHAVIOR OF INTERFERENCE IN TOTAL-POWER-AND-INTERFERENCE-LIMITED SCENARIO

Since $\mathcal{I}_{K_N}$ is a positive random variable, it is enough to show that $\lim_{N\to\infty}\mathsf{E}\left[\mathcal{I}_{K_N}\right]=0$ for K_N increasing to infinity at a rate $K_N = o\left(N\right)$ as N goes to infinity. We can upper bound $\mathcal{I}_{K_N}$ as

$$\begin{aligned}\mathcal{I}_{K_N} &= g_{i^\star_{K_N}} P^\star_{i^\star_{K_N},K_N}\left(\boldsymbol{h},\boldsymbol{g}\right)\\ &= g_{i^\star_{K_N}}\left(\frac{1}{\lambda_N+\mu_N g_{i^\star_{K_N}}}-\frac{1}{h_{i^\star_{K_N}}}\right)^{+}\\ &\leq \frac{g_{K_N:N}}{\lambda_N}.\end{aligned}$$

Hence, using the fact that $\liminf_{N\to\infty}\lambda_N > 0$, it is enough to show that $\lim_{N\to\infty}\mathsf{E}\left[g_{K_N:N}\right]=0$. To this end, for any given $\epsilon > 0$, we can upper bound $\mathsf{E}\left[g_{K_N:N}\right]$ as

$$\begin{aligned}\mathsf{E}\left[g_{K_N:N}\right] &= \mathsf{E}\left[g_{K_N:N}1_{\{g_{K:N}<\epsilon\}}\right]+\mathsf{E}\left[g_{K_N:N}1_{\{\epsilon\leq g_{K:N}<N\}}\right]+\sum_{i=1}^{\infty}\mathsf{E}\left[g_{K_N:N}1_{\{N^i\leq g_{K:N}<N^{i+1}\}}\right]\\ &\leq \epsilon + N\mathsf{Pr}\left\{g_{K_N:N}\geq\epsilon\right\}+\sum_{i=1}^{\infty}N^{i+1}\mathsf{Pr}\left\{g_{K_N:N}\geq N^i\right\}. \quad (36)\end{aligned}$$

Below, we will show that $\mathsf{Pr}\left\{g_{K_N:N}\geq\epsilon\right\}$ and $\mathsf{Pr}\left\{g_{K_N:N}\geq N^i\right\}$ can be asymptotically bounded as $\mathsf{Pr}\left\{g_{K_N:N}\geq\epsilon\right\}\leq \mathrm{e}^{-\Theta(N)}$ and $\mathsf{Pr}\left\{g_{K_N:N}\geq N^i\right\}\leq\mathrm{e}^{-\Theta\left(N^{in+1}\right)}$. Assuming for a while that these asymptotic bounds hold, $\mathsf{E}\left[g_{K_N:N}\right]$ can be upper bounded as

$$\begin{aligned}\mathsf{E}\left[g_{K_N:N}\right] &\leq \epsilon + N\mathrm{e}^{-\Theta(N)}+\sum_{i=1}^{\infty}N^{i+1}\mathrm{e}^{-\Theta\left(N^{in+1}\right)}\\ &\leq \epsilon + N\mathrm{e}^{-\Theta(N)}+N\mathrm{e}^{-N}\sum_{i=1}^{\infty}N^{i}\mathrm{e}^{-\Theta\left(N^{in}\right)},\end{aligned}$$

which implies $\limsup_{N\to\infty} \mathsf{E}\left[g_{K_N:N}\right] = 0$ and completes the proof.

Now, we derive the aforementioned asymptotic expansions for $\mathsf{Pr}\left\{g_{K_N:N} \geq \epsilon\right\}$ and $\mathsf{Pr}\left\{g_{K_N:N} \geq N^i\right\}$. Note that $\mathsf{Pr}\left\{g_{K_N:N} \leq x\right\} = \sum_{i=K_N}^{N} \binom{N}{i} F_g^i\left(x\right)\left(1-F_g\left(x\right)\right)^{N-i}$ [22]. Therefore, for all $x > 0$ and N large enough, $\mathsf{Pr}\left\{g_{K_N:N} \geq x\right\}$ can be upper bounded as

$$\begin{aligned}
\mathsf{Pr}\left\{g_{K_N:N} \geq x\right\} &= \sum_{i=0}^{K_N-1} \binom{N}{i} F_g^i\left(x\right)\left(1-F_g\left(x\right)\right)^{N-i} \\
&\overset{(a)}{\leq} K_N \binom{N}{K_N}\left(1-F_g\left(x\right)\right)^{N-K_N} \\
&\overset{(b)}{\leq} K_N \sqrt{\frac{N}{\pi K_N\left(N-K_N\right)}}\, 2^{NH_b\left(\frac{K_N}{N}\right)}\left(1-F_g\left(x\right)\right)^{N-K_N} \\
&\leq N 2^{NH_b\left(\frac{K_N}{N}\right)}\left(1-F_g\left(x\right)\right)^{N-K_N}, \qquad (37)
\end{aligned}$$

where (a) follows from the fact that $K_N < \left(N+1\right)F_g\left(x\right)-1$ for $x>0$ and N large enough[4], (b) follows from $\binom{N}{K_N} \leq 2^{NH_b\left(\frac{K_N}{N}\right)}\sqrt{\frac{N}{\pi K_N\left(N-K_N\right)}}$ for $K_N \notin \{0, N\}$, where $H_b(\cdot)$ is the binary entropy function [29]. Using (37), $\mathsf{Pr}\left\{g_{K_N:N} \geq \epsilon\right\}$ can be upper bounded as

$$\begin{aligned}
\mathsf{Pr}\left\{g_{K_N:N} \geq \epsilon\right\} &\leq N 2^{NH_b\left(\frac{K_N}{N}\right)}\left(1-F_g\left(\epsilon\right)\right)^{N-K_N} \\
&= \mathrm{e}^{N\left(\left(1-\frac{K_N}{N}\right)\log\left(1-F_g(\epsilon)\right)+H_b\left(\frac{K_N}{N}\right)\log(2)+\frac{\log(N)}{N}\right)} \\
&= \mathrm{e}^{\Theta(-N)}. \qquad (38)
\end{aligned}$$

Similarly, for any given $\epsilon > 0$ and N large enough, $\mathsf{Pr}\left\{g_{K_N:N} \geq N^i\right\}$ can be upper bounded as

$$\begin{aligned}
\mathsf{Pr}\left\{g_{K_N:N} \geq N^i\right\} &\leq N 2^{NH_b\left(\frac{K_N}{N}\right)}\left(1-F_g\left(N^i\right)\right)^{N-K_N} \\
&\leq N 2^{NH_b\left(\frac{K_N}{N}\right)}\left(\left(1+\epsilon\right)\alpha_h N^{il_h}\mathrm{e}^{-\beta_h N^{in_h}+H(N^i)}\right)^{N-K_N} \\
&= \mathrm{e}^{\left(\log(N)+NH_b\left(\frac{K_N}{N}\right)\log(2)+(N-K_N)(\log(1+\epsilon)+\log(\alpha_h N^{il_h})-\beta_h N^{in_h}+H(N^i))\right)} \\
&= \mathrm{e}^{N^{in_h+1}\left(\left(1-\frac{K_N}{N}\right)\left(-\beta_h+\frac{\log(1+\epsilon)+\log\left(\alpha_h N^{il_h}\right)+H\left(N^i\right)}{N^{in_h}}\right)+\frac{\log(N)+NH_b\left(\frac{K_N}{N}\right)\log(2)}{N^{in_h+1}}\right)} \\
&= \mathrm{e}^{\Theta(-N^{in+1})}. \qquad (39)
\end{aligned}$$

APPENDIX D

THROUGHPUT SCALING IN INTERFERENCE-LIMITED SCENARIO

In this appendix, we first establish the secondary network throughput scaling behavior for $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$. Then, we will use this result to obtain an upper bound on the secondary network throughput in $\mathrm{CoS}_{\mathrm{IL}}^{K}$.

---

[4] Let $b\left(k;n,p\right)$ be the Binomial function with parameters $n \in \mathbb{N}$ and $p \in (0,1)$, which is defined as $b\left(k;n,p\right) = \binom{n}{k}p^k\left(1-p\right)^{n-k}$. Then, $b\left(k;n,p\right)$ first increases, and then decreases as a function of k, reaching its maximum at $k = m^\star$, where $m^\star$ is an integer such that $\left(n+1\right)p-1 < m^\star \leq \left(n+1\right)p$. If $\left(n+1\right)p$ is an integer, then $m^\star = \left(n+1\right)p$, and $b\left(m^\star-1;n,p\right) = b\left(m^\star;n,p\right)$ [30].

To this end, we need to study the asymptotic behavior of $X_N^\star\left(0,\mu_N\right)=\max_{1\leq i\leq N}\frac{h_i}{\mu_N g_i}$ when N grows large. Similar to our proof for TPIL networks given in Appendix B, we start our analysis by deriving the scaling behavior of $\tilde{R}\left(N,0,\mu\right)=\mathsf{E}\left[\log\left(X_N^\star\left(0,\mu\right)\right)1_{\left\{X_N^\star(0,\mu)\geq 1\right\}}\right]$, where μ is a fixed positive constant. In the next lemma, we characterize the asymptotic tail behavior of the random variable $X_i\left(0,\mu\right)=\frac{h_i}{\mu g_i}$, where $X_i\left(\lambda,\mu\right)$ is defined as $X_i\left(\lambda,\mu\right)=\frac{h_i}{\lambda+\mu g_i}$. Then, we will use this lemma to establish the concentration behavior of $X_N^\star\left(0,\mu\right)$, and thereby to obtain the scaling behavior of $\tilde{R}\left(N,0,\mu\right)$. Throughout this appendix, we assume that h_i's and g_i's are distributed according to $F_h\left(x\right)$ and $F_g\left(x\right)$, respectively, where $F_h\left(x\right)$ and $F_g\left(x\right)$ belong to the class $\mathcal{C}$ distributions.

Lemma 7: Let $F_{X_i(0,\mu)}(x)$ be the CDF of $X_i\left(0,\mu\right)=\frac{h_i}{\mu g_i}$. Then, $\lim_{x\rightarrow\infty}\frac{1-F_{X_i(0,\mu)}(x)}{\xi x^{-\gamma_g}}=1$, where $\xi=\frac{\eta_g\mathsf{E}\left[h_i^{\gamma_g}\right]}{\mu^{\gamma_g}}$, and η_g and γ_g are positive constants derived from the behavior of the distribution function of g_i near the origin.

Proof: To prove this lemma, we use some results from [28] characterizing the asymptotic tail behavior for the product of two independent random variables. Let U and V be two independent random variables with distribution functions $F_U\left(x\right)$ and $F_V\left(x\right)$, respectively. The asymptotic tail behavior of the distribution function $F_{UV}(x)$ of UV is given by $\lim_{x\rightarrow\infty}\frac{1-F_{UV}(x)}{C\mathsf{E}[U^\theta]x^{-\theta}}=1$ if the following conditions hold (*i.e.*, Theorem 4 in [28]): *i-)* $\lim_{x\rightarrow\infty}\frac{1-F_V(x)}{Cx^{-\theta}}=1$ for some positive constants $C>0$ and $\theta>0$, *ii-)* $1-F_U\left(\phi\left(x\right)\right)=o\left(x^{-\theta}\right)$ as x tends to infinity for some $\phi\left(x\right)$ such that $\phi\left(x\right)=o\left(x\right)$ as x grows large, and *iii-)* $\mathsf{E}\left[U^\theta\right]<\infty$. To derive the asymptotic behavior of $\frac{h_i}{\mu g_i}$, it is enough to show that $\frac{1}{\mu g_i}$ and h_i satisfy these conditions. Since $F_g(x)$ varies regularly near the origin, the tail of the distribution function of $\frac{1}{\mu g_i}$ varies regularly, *i.e.*, $\lim_{x\rightarrow\infty}\frac{\mathsf{Pr}\left\{\frac{1}{\mu g_i}>x\right\}}{\eta_g\left(\mu x\right)^{-\gamma_g}}=1$, implying $C=\frac{\eta_g}{\mu^{\gamma_g}}$ and $\theta=\gamma_g$ above. Choosing $\phi(x)$ as $\phi(x)=x^\delta$ for some $\delta\in(0,1)$, we have $1-F_h\left(x^\delta\right)=O\left(\alpha_h x^{\delta l_h}\mathrm{e}^{\left(-\beta_h x^{\delta n_h}+H\left(x^\delta\right)\right)}\right)=o\left(x^{-\gamma_g}\right)$. Since the tail of $1-F_h(x)$ decays exponentially to zero, it also follows that $\mathsf{E}\left[h_i^{\gamma_g}\right]<\infty$, which completes the proof. ■

Now, we provide a key lemma that will enable us to upper and lower bound the secondary network scaling behavior in $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$.

Lemma 8: For $\mu>0$, we have $\lim_{N\rightarrow\infty}\frac{\tilde{R}(N,0,\mu)}{\frac{1}{\gamma_g}\log(\xi N)}=1$.

Proof: Let $\tilde{X}_N^\star\left(0,\mu\right)=\frac{\log(X_N^\star(0,\mu))}{\frac{1}{\gamma_g}\log(\xi N)}1_{\left\{X_N^\star(0,\mu)\geq 1\right\}}$ where $X_N^\star\left(0,\mu\right)=\max_{1\leq i\leq N}X_i\left(0,\mu\right)$. It is sufficient to show that $\lim_{N\rightarrow\infty}\mathsf{E}\left[\tilde{X}_N^\star\left(0,\mu\right)\right]=1$. We start our analysis by proving that $\tilde{X}_N^\star\left(0,\mu\right)\xrightarrow{i.p.}1$ as N tends to infinity. Using Lemma 7, the tail behavior of $F_{X_i(0,\mu)}\left(x\right)$ is characterized by $G\left(x\right)=\frac{x^{\gamma_g}}{\xi}$, where $\xi=\frac{\eta_g\mathsf{E}\left[h_i^{\gamma_g}\right]}{\mu^{\gamma_g}}$. Hence, $G^{-1}\left(x\right)=\left(\xi x\right)^{\frac{1}{\gamma_g}}$. Using Lemma 2, we have

$$\begin{aligned}\mathsf{Pr}\left\{G^{-1}\left(\xi^{-\epsilon}N^{1-\epsilon}\right)<X_N^\star\left(0,\mu\right)\leq G^{-1}\left(\xi^{\epsilon}N^{1+\epsilon}\right)\right\} &= \mathsf{Pr}\left\{\left(\xi N\right)^{\frac{1}{\gamma_g}(1-\epsilon)}<X_N^\star\left(0,\mu\right)\leq\left(\xi N\right)^{\frac{1}{\gamma_g}(1+\epsilon)}\right\}\\ &= 1-\Theta\left(\frac{1}{N^\epsilon}\right),\end{aligned}\tag{40}$$

which implies $\tilde{X}_N^\star\left(0,\mu\right)\xrightarrow{i.p.}1$ as N grows large. Since convergence in probability does not always imply convergence in mean, we need to show that $\left\{\tilde{X}_N^\star\left(0,\mu\right)\right\}_{N=1}^\infty$ is uniformly integrable to complete the proof. To this end, we will show that for all $\epsilon_1>0$ and $\epsilon_2>0$, there exist large enough positive constants C_0 and N_0 such that

$$\sup_{N\geq N_0} \mathsf{E}\left[\tilde{X}_N^{\star}(0,\mu)\, 1_{\left\{\tilde{X}_N^{\star}(0,\mu)>C\right\}}\right] \;\leq\; (1+\epsilon_1)(1+\epsilon_2)\frac{\xi N_0}{(\xi N_0)^C}\sum_{i=0}^{\infty}\frac{(i+2)}{(\xi N_0)^{iC}}, \tag{41}$$

for $C \geq C_0$. Since the proof of this fact is similar to the proof of (23), we just give the main steps below.

For $C > 0$, $\mathsf{E}\left[\tilde{X}_N^{\star}(0,\mu)\, 1_{\left\{\tilde{X}_N^{\star}(0,\mu)>C\right\}}\right]$ can be upper bounded as

$$\begin{aligned} \mathsf{E}\left[\tilde{X}_N^{\star}(0,\mu)\, 1_{\left\{\tilde{X}_N^{\star}(0,\mu)>C\right\}}\right] &\leq \sum_{i=1}^{\infty}(i+1)\, C \mathsf{Pr}\left\{iC < \tilde{X}_N^{\star}(0,\mu) \leq (i+1)\,C\right\} \\ &\leq \sum_{i=1}^{\infty}(i+1)\, C \mathsf{Pr}\left\{(\xi N)^{\frac{iC}{\gamma_g}} < X_N^{\star}(0,\mu)\right\}. \end{aligned} \tag{42}$$

For $\epsilon_1 > 0$, $\epsilon_2 > 0$ and N large enough, $\mathsf{Pr}\left\{(\xi N)^{\frac{iC}{\gamma_g}} < X_N^{\star}(0,\mu)\right\}$ can be upper bounded as

$$\begin{aligned} \mathsf{Pr}\left\{(\xi N)^{\frac{iC}{\gamma_g}} < X_N^{\star}(0,\mu)\right\} &\overset{(a)}{\leq} 1 - \left(1 - \frac{\xi(1+\epsilon_1)}{(\xi N)^{iC}}\right)^N \\ &= 1 - \mathrm{e}^{N \log\left(1 - \frac{\xi(1+\epsilon_1)}{(\xi N)^{iC}}\right)} \\ &\overset{(b)}{\leq} 1 - \mathrm{e}^{-(1+\epsilon_1)(1+\epsilon_2)\frac{\xi N}{(\xi N)^{iC}}}. \\ &\overset{(c)}{\leq} (1+\epsilon_1)(1+\epsilon_2)\frac{\xi N}{(\xi N)^{iC}}, \end{aligned} \tag{43}$$

where (a) follows from the fact that for all $\epsilon_1 > 0$ and x large enough, $F_{X(0,\mu)}(x)$ can be lower bounded as $F_{X(0,\mu)}(x) \geq 1 - \frac{\xi(1+\epsilon_1)}{x^{\gamma_g}}$ (recall $\lim_{x\rightarrow\infty}\frac{1-F_{X(0,\mu)}(x)}{\xi x^{-\gamma_g}} = 1$), (b) follows form the fact that for all $\epsilon_2 > 0$ and x small enough, $\log(1-x)$ can be lower bounded as $\log(1-x) \geq -(1+\epsilon_2)\,x$ since $\lim_{x\downarrow 0}\frac{\log(1-x)}{x} = -1$, and (c) follows from the fact e^{-x} can be lower bounded as $\mathrm{e}^{-x} \geq 1 - x$ for $x > 0$.

Note that $\sum_{i=1}^{\infty}(i+1)\, C(1+\epsilon_1)(1+\epsilon_2)\frac{\xi N}{(\xi N)^{iC}}$ is a decreasing function of N for $C > 1$. Thus, for given $\epsilon_1 > 0$ and $\epsilon_2 > 0$, we can find large enough constants N_0 and C_0 such that

$$\sup_{N\geq N_0} \mathsf{E}\left[\tilde{X}_N^{\star}(0,\mu)\, 1_{\left\{\tilde{X}_N^{\star}(0,\mu)>C\right\}}\right] \;\leq\; C(1+\epsilon_1)(1+\epsilon_2)\frac{\xi N_0}{(\xi N_0)^C}\sum_{i=0}^{\infty}\frac{(i+2)}{(\xi N_0)^{iC}},$$

for $C \geq C_0$. ■

The next lemma characterizes the asymptotic behavior of the Lagrange multiplier μ_N as N becomes large. Later, we will use this result to provide upper and lower bounds for $\tilde{R}(N,0,\mu)$. This result will also be helpful to conclude the logarithmic effect of Q_{ave} on the secondary network throughput under $\text{CoS}_{\text{IL}}^{\text{F}}$.

Lemma 9: Let μ_N be the Lagrange multiplier corresponding to the average interference power constraint in $\text{CoS}_{\text{IL}}^{\text{F}}$. Then, $\lim_{N\rightarrow\infty}\mu_N = \frac{1}{Q_{\text{ave}}}$.

Proof: First, we show that $\liminf_{N\rightarrow\infty}\mu_N > 0$ by contradiction. Assume $\liminf_{N\rightarrow\infty}\mu_N = 0$. This means that, for any given $\epsilon > 0$, we can find a subsequence $\{N_j\}_{j=1}^{\infty}$ such that $\mu_{N_j} \leq \epsilon$ for N_j large enough. The average interference power for N_j large enough can be lower bounded as $\mathsf{E}\left[\left(\frac{1}{\mu_{N_j}} - \frac{1}{X^\star_{N_j}(0,1)}\right)^+\right] \geq \mathsf{E}\left[\left(\frac{1}{\epsilon} - \frac{1}{X^\star_{N_j}(0,1)}\right)^+\right]$. Note that $\left(\frac{1}{\epsilon} - \frac{1}{X^\star_{N_j}(0,1)}\right)^+ \xrightarrow{i.p.} \frac{1}{\epsilon}$. Applying Fatou's lemma , we have

$$\begin{aligned}\liminf_{N_j\to\infty} \mathsf{E}\left[\left(\frac{1}{\mu_{N_j}} - \frac{1}{X^\star_{N_j}(0,1)}\right)^+\right] &\geq \liminf_{N_j\to\infty} \mathsf{E}\left[\left(\frac{1}{\epsilon} - \frac{1}{X^\star_{N_j}(0,1)}\right)^+\right] \\ &\geq \frac{1}{\epsilon},\end{aligned}$$

which implies that the average interference power constraint will be violated when N_j is large enough if we choose ϵ sufficiently small. Thus, we conclude that $\liminf_{N\to\infty} \mu_N > 0$. Now, we will complete the proof by using the fact that μ_N cannot be arbitrarily close to zero as N grows large. The average interference power constraint can be expressed as $\mu_N = \frac{1}{Q_{\text{ave}}}\mathsf{E}\left[\left(1 - \frac{1}{X^\star_N(0,\mu_N)}\right)^+\right]$. Since $\liminf_{N\to\infty} \mu_N > 0$, the desired result follows from the dominated convergence theorem.[5] ■

A. Proof of Throughput Scaling in CoS$_{\text{IL}}^{\text{F}}$

Now, we establish the secondary network throughput scaling behavior under the communication scenario CoS$_{\text{IL}}^{\text{F}}$. First, we note that $\tilde{R}(N,0,\mu)$ is a decreasing function of μ. Therefore, for any given $\epsilon > 0$, we can find a constant N_0 large enough such that $R_{\text{IL}}^{\text{F}}(N)$ can be upper and lower bounded as

$$\tilde{R}\left(N,0,\frac{1+\epsilon}{Q_{\text{ave}}}\right) \leq R_{\text{IL}}^{\text{F}}(N) \leq \tilde{R}\left(N,0,\frac{1-\epsilon}{Q_{\text{ave}}}\right) \tag{44}$$

for all $N \geq N_0$ since μ_N converges to $\frac{1}{Q_{\text{ave}}}$ as N becomes large. Using Lemma 8, for any $\epsilon > 0$ and N large enough, $R_{\text{IL}}^{\text{F}}(N)$ can be further upper and lower bounded as

$$(1-\epsilon)\frac{1}{\gamma_g}\log\left(\left(\frac{Q_{\text{ave}}}{1+\epsilon}\right)^{\gamma_g}\eta_g\mathsf{E}\left[h^{\gamma_g}\right]N\right) \leq R_{\text{IL}}^{\text{F}}(N) \leq (1+\epsilon)\frac{1}{\gamma_g}\log\left(\left(\frac{Q_{\text{ave}}}{1-\epsilon}\right)^{\gamma_g}\eta_g\mathsf{E}\left[h^{\gamma_g}\right]N\right), \tag{45}$$

where h is a generic random variable with CDF $F_h(x)$. Thus, we have

$$\lim_{N\to\infty}\frac{R_{\text{IL}}^{\text{F}}(N)}{\log(N)} = \frac{1}{\gamma_g}. \tag{46}$$

B. Proof of Throughput Scaling in CoS$_{\text{IL}}^{K}$

The secondary network sum-rate in CoS$_{\text{IL}}^{\text{F}}$ serves as an upper bound for the secondary network sum-rate in CoS$_{\text{IL}}^{K}$, *i.e.*, $R_{\text{IL}}^{K}(K_N) \leq R_{\text{IL}}^{\text{F}}(N)$, since more information is available at the SBS to perform power control and user scheduling under CoS$_{\text{IL}}^{\text{F}}$. Thus, we have $\limsup_{N\to\infty}\frac{R_{\text{IL}}^{K}(K_N)}{\log(N)} \leq \frac{1}{\gamma_g}$.

To prove the other direction, consider a sub-optimum power allocation policy $\hat{\boldsymbol{P}}_{K_N}^{\text{IL}}(\boldsymbol{g})$, which only depends on interference channel power gains, for a secondary network under CoS$_{\text{IL}}^{K}$ in which SU-i transmits with power

---

[5] Note that Lebesgue dominated convergence theorem remains valid if almost sure convergence is replaced with convergence in probability in its hypothesis [31].

$\hat{P}^{\rm IL}_{i,K_N}\left(\boldsymbol{g}\right) = \frac{Q_{\rm ave}}{g_i} 1_{\left\{g_i=\min_{1\leq i\leq K_N} g_{\pi(i)}\right\}}$. Note that $\min_{1\leq i\leq K_N} g_{\pi(i)} = \min_{1\leq i\leq N} g_i = g_{\min}(N)$. The average interference power at the PBS using $\hat{\boldsymbol{P}}^{\rm IL}_{K_N}$ is given by $\mathsf{E}\left[\sum_{i=1}^{N} \hat{P}^{\rm IL}_{i,K_N} g_i\right] = Q_{\rm ave}$. Thus, $\hat{\boldsymbol{P}}^{\rm IL}_{K_N}$ satisfies the average interference power constraint, and therefore it is a feasible power allocation policy for a secondary network under ${\rm CoS}^{K}_{\rm IL}$. Let $\hat{R}_{\rm IL}\left(K_N\right)$ be the secondary network sum-rate using $\hat{\boldsymbol{P}}^{\rm IL}_{K_N}$. $\hat{R}_{\rm IL}\left(K_N\right)$ can be lower bounded as

$$\hat{R}_{\rm IL}\left(K_N\right) \quad \geq \quad \log\left(Q_{\rm ave}\right) + \mathsf{E}\left[\log\left(h\right)\right] + \mathsf{E}\left[\log\left(\frac{1}{g_{\min}(N)}\right)\right],$$

where h is a generic random variable with CDF $F_h(x)$. Using arguments similar to the ones used to prove Lemma 8, it is easy to show that $\lim_{N\rightarrow\infty} \frac{\mathsf{E}\left[\log\left(\frac{1}{g_{\min}(N)}\right)\right]}{\log(N)} = \frac{1}{\gamma_g}$ since $\frac{1}{g_{\min}(N)} = \max_{1\leq i\leq N} \frac{1}{g_i}$ and the tail behavior of $\frac{1}{g_i}$ is characterized by $\lim_{x\rightarrow\infty} \frac{\mathsf{Pr}\left\{\frac{1}{g_i}\geq x\right\}}{\eta_g x^{-\gamma_g}} = 1$. Also, we have $\left|\mathsf{E}\left[\log\left(h\right)\right]\right| < \infty$[6]. Thus, $\liminf_{N\rightarrow\infty} \frac{\hat{R}_{\rm IL}(K_N)}{\log(N)} \geq \frac{1}{\gamma_g}$. Since $\hat{\boldsymbol{P}}^{\rm IL}_{K_N}$ is a sub-optimal power allocation policy for a secondary network under ${\rm CoS}^{K}_{\rm IL}$, we have $\hat{R}_{\rm IL}\left(K_N\right) \leq R^{K}_{\rm IL}\left(K_N\right)$ and therefore $\liminf_{N\rightarrow\infty} \frac{R^{K}_{\rm IL}(K_N)}{\log(N)} \geq \frac{1}{\gamma_g}$, which completes the proof.

APPENDIX E

THROUGHPUT SCALING IN INDIVIDUAL-POWER-AND-INTERFERENCE-LIMITED SCENARIO

In this appendix, we first establish the secondary network throughput scaling behavior for ${\rm CoS}^{\rm F}_{\rm IPIL}$. Then, we use this result to obtain an upper bound on the secondary network throughput scaling in ${\rm CoS}^{K}_{\rm IPIL}$. Below, we prove two key lemmas that will facilitate the proof of Theorem 4. The next lemma establishes the throughput scaling behavior for a primary MAC network. This result in turn leads to an upper bound on the sum-rate for ${\rm CoS}^{\rm F}_{\rm IPIL}$.

Lemma 10: Consider a primary MAC network containing N users with symmetric individual average transmit power constraints equal to $P_{\rm ave}$ and i.i.d. channel power gains $\left\{h_i\right\}_{i=1}^{N}$ whose common CDF belongs to the class $\mathcal{C}$ distributions. Let $R_{\rm IPL}\left(N\right)$ be the sum-rate of this network when transmit powers of users are optimally allocated. Then, $\lim_{N\rightarrow\infty} \frac{R_{\rm IPL}(N)}{\log(N)} = 1$.

Proof: $R_{\rm IPL}\left(N\right)$ can be expressed as $R_{\rm IPL}\left(N\right) = \mathsf{E}\left[\log\left(\frac{h^{\star}_N}{\lambda_N}\right) 1_{\left\{\frac{h^{\star}_N}{\lambda_N}\geq 1\right\}}\right]$, where λ_N is the Lagrange multiplier associated with individual power constraints. As above, we define $h^{\star}_N$ as $h^{\star}_N = \max_{1\leq i\leq N} h_i$. $R_{\rm IPL}\left(N\right)$ can be upper and lower bounded as

$$\log\left(\frac{1}{\lambda_N}\right) + \mathsf{E}\left[\log\left(h^{\star}_N\right)\right] \leq R_{\rm IPL}\left(N\right) \leq \log\left(\frac{1}{\lambda_N}\right) + \mathsf{E}\left[\log\left(h^{\star}_N\right) 1_{\left\{h^{\star}_N\geq 1\right\}}\right].$$

Below, we will show that $\lim_{N\rightarrow\infty} N\lambda_N = \frac{1}{P_{\rm ave}}$. This will complete the proof since $\mathsf{E}\left[\log\left(h^{\star}_N\right)\right]$ scales double logarithmically with N (*i.e.,* see Lemma 3 in Appendix B). The average transmit power of the ith user can be written as

---

[6] Using Jensen inequality, we have $\mathsf{E}\left[\log\left(h\right)\right] \leq \log\left(\mathsf{E}\left[h\right]\right) = 0$. Also, $\mathsf{E}\left[\log\left(h\right)\right]$ can be lower bounded as $\mathsf{E}\left[\log\left(h\right)\right] \geq \mathsf{E}\left[\log\left(h\right) 1_{\left\{h\leq 1\right\}}\right]$. Using integration by part and the fact that $F_g\left(x\right)$ varies regularly around origin, it is easy to show that $\left|\mathsf{E}\left[\log\left(h\right) 1_{\left\{h\leq 1\right\}}\right]\right| < \infty$.

$$\begin{aligned}\mathsf{E}\left[\left(\frac{1}{\lambda_N}-\frac{1}{h_i}\right)^{+}1_{\{h_i=h_N^{\star}\}}\right] &= \frac{1}{N}\mathsf{E}\left[\left(\frac{1}{\lambda_N}-\frac{1}{h_N^{\star}}\right)1_{\{h_N^{\star}\geq\lambda_N\}}\right] \\ &= \frac{1}{N\lambda_N}\left(\mathsf{Pr}\left(h_N^{\star}\geq\lambda_N\right)-\lambda_N\mathsf{E}\left[\frac{1}{h_N^{\star}}1_{\{h_N^{\star}\geq\lambda_N\}}\right]\right) \qquad (47)\end{aligned}$$

since channel power gains are i.i.d. Note that λ_N is chosen such that the average tranmit power constraint is satisfied with equality, *i.e.*, $\mathsf{E}\left[\left(\frac{1}{\lambda_N}-\frac{1}{h_i}\right)^{+}1_{\{h_i=h_N^{\star}\}}\right]=P_{\text{ave}}$. Thus, (47) implies that $\lambda_N\leq\frac{1}{NP_{\text{ave}}}$, and λ_N converges to zero as N becomes large. This convergence result further implies that $\lim_{N\to\infty}\mathsf{Pr}\left\{h_N^{\star}\geq\lambda_N\right\}=1$. Hence, it is enough to show that $\mathsf{E}\left[\frac{1}{h_N^{\star}}1_{\{h_N^{\star}\geq\lambda_N\}}\right]$ converges to zero as N tends to infinity to complete the proof. From (22), we directly have $\frac{1}{h_N^{\star}}1_{\{h_N^{\star}\geq\lambda_N\}}$ converging to zero in probability. Using arguments similar to the ones used in Appendices B and D above, it can also be shown that $\left\{\frac{1}{h_N^{\star}}1_{\{h_N^{\star}\geq\lambda_N\}}\right\}_{N=1}^{\infty}$ is a uniformly integrable collection of random variables, which finishes the proof. ■

In the next lemma, we establish the asymptotic scaling behavior of $\mathsf{E}\left[g_{\min}(N)\right]$, where $g_{\min}(N)=\min_{1\leq i\leq N}g_i$, as N grows large. Later, this result will be helpful in the process of obtaining lower bounds for the sum-rate of secondary networks under $\text{CoS}_{\text{IPIL}}^{\text{F}}$ and $\text{CoS}_{\text{IPIL}}^{K}$.

Lemma 11: Let $g_{\min}(N)=\min_{1\leq i\leq N}g_i$. Then,

$$\lim_{N\to\infty}\frac{\mathsf{E}\left[g_{\min}(N)\right]}{F_g^{-1}\left(\frac{1}{N}\right)}=\Gamma\left(1+\frac{1}{\gamma_g}\right),$$

where $\Gamma\left(\cdot\right)$ is the Gamma function.

Proof: Observe that $F_g^{-1}(0)=0$ and $\lim_{x\downarrow 0}\frac{F_g(\epsilon x)}{F_g(x)}=\epsilon^{\gamma_g}$ for $\epsilon>0$, *i.e.*, see Definition 2.1. Hence, the sequence of random variables $\left\{\frac{g_{\min}(N)}{F_g^{-1}\left(\frac{1}{N}\right)}\right\}_{N=1}^{\infty}$ converges in distribution to a Weibull distributed random variable with shape parameter γ_g and scale parameter 1, *i.e.*, to the CDF $F\left(x\right)=1-\mathrm{e}^{-x^{\gamma_g}}$ for $x\geq 0$ [27]. Applying Fatou's lemma, we have $\liminf_{N\to\infty}\frac{\mathsf{E}\left[g_{\min}(N)\right]}{F_g^{-1}\left(\frac{1}{N}\right)}\geq\mathsf{E}\left[W\right]=\Gamma\left(1+\frac{1}{\gamma_g}\right)$.

To show the other direction, we write $\mathsf{E}\left[g_{\min}(N)\right]$ as

$$\mathsf{E}\left[g_{\min}(N)\right]=\int_0^{\epsilon_1}\left(1-F_g(x)\right)^N dx+\int_{\epsilon_1}^{N}\left(1-F_g(x)\right)^N dx+\sum_{i=1}^{\infty}\int_{N^i}^{N^{(i+1)}}\left(1-F_g(x)\right)^N dx \qquad (48)$$

for all $\epsilon_1>0$. For all ϵ_2 belonging to $(0,1)$ and ϵ_1 small enough, $\int_0^{\epsilon_1}\left(1-F_g(x)\right)^N dx$ can be upper bounded as

$$\begin{aligned}\int_0^{\epsilon_1}\left(1-F_g(x)\right)^N dx &\overset{\text{(a)}}{\leq} \int_0^{\epsilon_1}\left(1-\left(1-\epsilon_2\right)\eta_g x^{\gamma_g}\right)^N dx \\ &= \int_0^{\epsilon_1}\mathrm{e}^{N\log\left(1-(1-\epsilon_2)\eta x^{\gamma_g}\right)}dx \\ &\overset{\text{(b)}}{\leq} \int_0^{\epsilon_1}\mathrm{e}^{-N(1-\epsilon_2)\eta_g x^{\gamma_g}}dx \\ &= \frac{1}{\gamma_g}\int_0^{\epsilon_1^{\gamma_g}}x^{\frac{1}{\gamma_g}-1}\mathrm{e}^{-N(1-\epsilon_2)\eta_g x}dx,\end{aligned}$$

where (a) follows from Definition 2.1, and (b) follows from that fact that $\log(1-x) \leq -x$ for $0 \leq x < 1$. Applying Watson's lemma [32], we have $\lim_{N\to\infty} \frac{1}{\gamma_g} \frac{\int_0^{\epsilon_1^{\gamma_g}} x^{\frac{1}{\gamma_g}-1} \mathrm{e}^{-N(1-\epsilon_2)\eta_g x} dx}{F_g^{-1}\left(\frac{1}{N}\right)} = \frac{\Gamma\left(1+\frac{1}{\gamma_g}\right)}{1-\epsilon_2}$ for all $\epsilon_2 > 0$, which implies $\limsup_{N\to\infty} \frac{\int_0^{\epsilon_1} (1-F_g(x))^N dx}{F_g^{-1}\left(\frac{1}{N}\right)} \leq \Gamma\left(1+\frac{1}{\gamma_g}\right)$. To complete the proof, it is enough to show that the second and third terms in (48) decay to zero faster than $F_g^{-1}\left(\frac{1}{N}\right)$, *i.e.*, they can be asymptotically expressed as $o\left(F_g^{-1}\left(\frac{1}{N}\right)\right)$. $\int_{\epsilon_1}^{N} (1-F_g(x))^N dx$ can be upper bounded as

$$\begin{aligned} \int_{\epsilon_1}^{N} (1-F_g(x))^N dx &\leq N\left(1-F_g(\epsilon_1)\right)^N \\ &= N\mathrm{e}^{-\Theta(N)}. \end{aligned} \tag{49}$$

Thus, by recalling that F_g varies regularly around the origin, $\int_{\epsilon_1}^{N} (1-F_g(x))^N dx = o\left(F_g^{-1}\left(\frac{1}{N}\right)\right)$. Similarly, for all $\epsilon_3 > 0$ and N large enough, $\int_{N^i}^{N^{(i+1)}} (1-F_g(x))^N dx$ can be upper bounded as

$$\begin{aligned} \int_{N^i}^{N^{i+1}} (1-F_g(x))^N dx &\leq N^{i+1}\left(1-F_g\left(N^i\right)\right)^N \\ &\overset{\text{(a)}}{\leq} N^{i+1}\mathrm{e}^{N\log\left((1+\epsilon_3)\alpha_h N^{il_h}\mathrm{e}^{-\beta_h N^{in_h}+H\left(N^i\right)}\right)} \\ &= \mathrm{e}^{-N} N^{i+1}\mathrm{e}^{-\Theta\left(N^{in_h}\right)}, \end{aligned}$$

where (a) follows from Definition 2.1. Therefore, $\sum_{i=1}^{\infty}\int_{N^i}^{N^{(i+1)}} (1-F_g(x))^N = o\left(F_g^{-1}\left(\frac{1}{N}\right)\right)$, which completes the proof. ■

A. Proof of Throughput Scaling in $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$

We are now ready to establish the sum-rate scaling behavior for secondary networks under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$. By removing the individual power constraints, we obtain a secondary network under $\mathrm{CoS}_{\mathrm{IL}}^{\mathrm{F}}$. Thus, the sum-rate of a secondary network under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ is upper bounded by the sum-rate of the same network under $\mathrm{CoS}_{\mathrm{IL}}^{K}$, *i.e*, $R_{\mathrm{IPIL}}^{\mathrm{F}}(N) \leq R_{\mathrm{IL}}^{\mathrm{F}}(N)$. Hence, we have $\limsup_{N\to\infty} \frac{R_{\mathrm{IPIL}}^{\mathrm{F}}(N)}{\log(N)} \leq \frac{1}{\gamma_g}$. Similarly, by removing the average interference power constraint, we obtain a primary MAC network with individual power constraints. Therefore, the sum-rate under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$ is upper bounded by the sum-rate of a primary MAC network with the same individual power constraints, *i.e.*, $R_{\mathrm{IPIL}}^{\mathrm{F}}(N) \leq R_{\mathrm{IPL}}(N)$. Thus, we also have $\limsup_{N\to\infty} \frac{R_{\mathrm{IPIL}}^{\mathrm{F}}(N)}{\log(N)} \leq 1$, implying $\limsup_{N\to\infty} \frac{R_{\mathrm{IPIL}}^{\mathrm{F}}(N)}{\log(N)} \leq \min\left(1, \frac{1}{\gamma_g}\right)$.

To show the other direction, consider a sub-optimum power allocation policy $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ in which the transmit power of SU-i is given by the formula $\hat{P}_{i,N}^{\mathrm{IPIL}} = \epsilon N^{\min\left(1,\frac{1}{\gamma_g}\right)} 1_{\{g_i = g_{\min}(N)\}}$ for some $\epsilon > 0$. We will first show that $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ is a feasible power allocation policy for N large enough and an appropriate choice of ϵ. The average transmit power of SU-i under $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ is equal to $\mathsf{E}\left[\hat{P}_{i,N}^{\mathrm{IPIL}}\right] = \epsilon N^{\min\left(1,\frac{1}{\gamma_g}\right)-1}$ since the interference channel gains are i.i.d. Thus, for N large enough and a proper choice of ϵ, $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ satisfies individual average power constraints. The average interference power at the PBS under $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ is given by $\mathsf{E}\left[\sum_{i=1}^{N} g_i \hat{P}_{i,N}^{\mathrm{IPIL}}\right] = \epsilon N^{\min\left(1,\frac{1}{\gamma_g}\right)} \mathsf{E}\left[g_{\min}(N)\right]$. Using Lemma 11, the average interference power at the PBS can be asymptotically expressed as $\mathsf{E}\left[\sum_{i=1}^{N} g_i \hat{P}_{i,N}^{\mathrm{IPIL}}\right] =$

$\epsilon O\left(N^{\min\left(1,\frac{1}{\gamma_g}\right)-\frac{1}{\gamma_g}}\right)$. Thus, for N large enough and a proper choice of ϵ, $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ meets the average interference power constraint as well, and it is a feasible power allocation policy for a secondary network under $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$.

Let $\hat{R}_{\mathrm{IPIL}}\left(N\right)$ be the secondary network sum-rate under $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$. Note that $\hat{R}_{\mathrm{IPIL}}\left(N\right)$ serves as a lower bound for $R_{\mathrm{IPIL}}^{\mathrm{F}}\left(N\right)$ for an appropriate choice of ϵ and N large enough, *i.e.*, $\hat{R}_{\mathrm{IPIL}}\left(N\right) \leq R_{\mathrm{IPIL}}^{\mathrm{F}}\left(N\right)$ for N large enough. $\hat{R}_{\mathrm{IPIL}}\left(N\right)$ can be further lower bounded as

$$\begin{aligned}\hat{R}_{\mathrm{IPIL}}\left(N\right) &= \sum_{i=1}^{N}\mathsf{E}\left[\log\left(1+h_i\epsilon N^{\min\left(1,\frac{1}{\gamma_g}\right)}\right)\mathbb{1}_{\left\{g_i=g_{\min}(N)\right\}}\right]\\ &\geq \min\left(1,\frac{1}{\gamma_g}\right)\log\left(N\right)+\log\left(\epsilon\right)+\mathsf{E}\left[\log\left(h\right)\right],\end{aligned}$$

where h is a generic random variable with CDF $F_h(x)$. Therefore, $\liminf_{N\to\infty}\frac{R_{\mathrm{IPIL}}^{\mathrm{F}}(N)}{\log(N)} \geq \min\left(1,\frac{1}{\gamma_g}\right)$, which completes the proof.

B. Proof of Throughput Scaling in $\mathrm{CoS}_{\mathrm{IPIL}}^{K}$

Since more information is available at the SBS to perform power-control and user scheduling in $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$, we have $R_{\mathrm{IPIL}}^{K}\left(K_N\right) \leq R_{\mathrm{IPIL}}^{\mathrm{F}}\left(N\right)$, and therefore $\limsup_{N\to\infty}\frac{R_{\mathrm{IPIL}}^{K}(K_N)}{\log(N)} \leq \min\left(1,\frac{1}{\gamma_g}\right)$. To prove the other direction, consider a sub-optimum power allocation policy $\hat{\boldsymbol{P}}_{K_N}^{\mathrm{IPIL}}$ in which the transmit power of SU-i is given by $\hat{P}_{i,K_N}^{\mathrm{IPIL}} = \epsilon N^{\min\left(1,\frac{1}{\gamma_g}\right)}\mathbb{1}_{\left\{g_i=\min_{1\leq j\leq K_N} g_{\pi(j)}\right\}}$ for some $\epsilon > 0$. Let $\hat{R}_{\mathrm{IPIL}}\left(K_N\right)$ be the secondary network sum-rate under $\hat{\boldsymbol{P}}_{K_N}^{\mathrm{IPIL}}$. Similar to our feasibility proof for $\hat{\boldsymbol{P}}_N^{\mathrm{IPIL}}$ in $\mathrm{CoS}_{\mathrm{IPIL}}^{\mathrm{F}}$, we can show that for N large enough and a proper choice of ϵ, $\hat{\boldsymbol{P}}_{K_N}^{\mathrm{IPIL}}$ becomes a feasible power allocation policy. Hence, $\hat{R}_{\mathrm{IPIL}}\left(K_N\right) \leq R_{\mathrm{IPIL}}^{K}\left(K_N\right)$. It also follows that $\liminf_{N\to\infty}\frac{\hat{R}_{\mathrm{IPIL}}(K_N)}{\log(N)} \geq \min\left(1,\frac{1}{\gamma_g}\right)$. Therefore, $\liminf_{N\to\infty}\frac{R_{\mathrm{IPIL}}^{K}(K_N)}{\log(N)} \geq \min\left(1,\frac{1}{\gamma_g}\right)$, which completes the proof.
